

Incorporating Diagnostic Expectations into the New Keynesian Framework*

Jean-Paul L’Huillier[†] Sanjay R. Singh[‡] Donghoon Yoo[§]

March 2023

Abstract

Diagnostic expectations constitute a realistic behavioral model of inference. This paper shows that this approach to expectation formation can be productively integrated into the New Keynesian framework. Diagnostic expectations generate *endogenous* extrapolation in general equilibrium. We show that diagnostic expectations generate extra amplification in the presence of nominal frictions; a fall in aggregate supply generates a Keynesian recession; fiscal policy is more effective at stimulating the economy. We perform Bayesian estimation of a rich medium-scale model that incorporates consensus forecast data. Our estimate of the diagnosticity parameter is in line with previous studies. Moreover, we find empirical evidence in favor of the diagnostic model. Diagnostic expectations offer new propagation mechanisms to explain fluctuations.

Keywords: Heuristics, representativeness, general equilibrium, shocks, volatility.

1 Introduction

Diagnostic expectations (DE) have emerged as an important departure from rational expectations in macroeconomics and finance. Among the host of possible deviations from rational expectations, there are three broad reasons that make diagnostic expectations a leading alternative to consider for macroeconomic modeling. First, diagnostic expectations constitute a microfounded deviation immune to the Lucas critique. Second, this approach lends itself to a great deal of tractability, as a number of recent efforts in macroeconomics and finance have demonstrated (see Bordalo, Gennaioli, and Shleifer 2018; Bordalo, Gennaioli, Ma, and Shleifer 2020; Bordalo, Gennaioli, Shleifer, and Terry 2021, among others). Third, based on the pathbreaking and influential work on the “representativeness heuristic” by Kahneman and Tversky (1972), one ought to consider this behavioral model as fundamentally realistic, and thereby portable across fields of economics.¹

In this paper, we argue that diagnostic expectations can be productively incorporated into the New Keynesian (NK) framework. We demonstrate this claim in two parts, analytical and empirical. Analytically, using a three-equation NK model, we show how diagnostic expectations bring rich insights on three issues raised by the literature. Empirically, by integrating diagnostic expectations into a rich medium-scale DSGE model, we find that diagnostic expectations provide a superior fit of business cycle and consensus forecast data. Our analysis brings novel implications for the interpretation of fluctuations.

The first analytical issue we tackle is that of amplification and propagation in general equilibrium. As shown in previous work (Bordalo, Gennaioli, and Shleifer 2018, henceforth BGS), diagnostic expectations (DE) imply an extrapolation of current shocks into the future. Intuitively, this could generate extra volatility for endogenous variables. We show that this intuition is in fact not guaranteed. In the presence of nominal frictions (as in the NK model) DE generate extra volatility; in a frictionless representative agent real business cycle (RBC) model, general equilibrium channels shut down the effect of DE, and output is *less* volatile under DE than under rational expectations (RE).

The second issue considered is whether a fall in aggregate supply can cause a demand shortage. Since the onset of the COVID-19 pandemic, there is a renewed interest on whether supply-side disruptions can ultimately generate shortfalls in aggregate de-

¹Simply put, the representativeness heuristic is the general human tendency to over-estimate how representative a small sample is, a pattern documented in a large body of literature in psychology and behavioral economics. For a survey and more detailed discussion, see Kahneman, Slovic, and Tversky (1982).

mand (see Guerrieri, Lorenzoni, Straub, and Werning 2022; Fornaro and Wolf 2022; Caballero and Simsek 2021; Bilbiie and Melitz 2022, among others). Whereas the rational expectations NK (RE-NK) model generates the opposite prediction, we show that adding DE into the NK framework (DE-NK) allows for the possibility of “Keynesian supply shocks”: Following a negative supply shock, diagnostic agents extrapolate the shock into the future, and hence become excessively pessimistic. This pushes them to reduce consumption drastically, generating a Keynesian recession. Later, beliefs systematically revert, and the economy features a boom, as in the RE-NK model.

The third issue we tackle concerns government policy. We show how endogenous extrapolation arising from the evaluation of the inflation process by diagnostic agents can significantly raise the government spending multiplier. Current surprise inflation causes the diagnostic agent to expect future inflation, thereby reducing the subjective real interest rate. When the diagnosticity parameter is larger than the coefficient governing the reaction of the monetary authority to inflation, the DE-NK model generates a multiplier greater than 1 even with i.i.d. government spending shocks. We show how this analytical conclusion can be challenged by the degree of extrapolation of the exogenous shock process, which depends on the persistence of this shock. If the shock is persistent enough, the DE of future spending can completely crowd out current consumption and lead to a multiplier that is equal to 0, or even negative. Hence, the degree of diagnosticity allows the model to span a wide range of multipliers, highlighting the importance of the behavioral friction in this context.

On the empirical front, we let DE and RE compete within a medium-scale DSGE model. Using Bayesian methods, we evaluate the relative fitness of both approaches when applied to post-war U.S. data. We include both business cycle and forecast data in the estimation. In order to submit the behavioral expectational friction to a stringent empirical test, the model we consider contains a large number of benchmark frictions and shocks drawn from the seminal works by Christiano, Eichenbaum, and Evans (2005) and Smets and Wouters (2007). For the same reason, we also include news shocks and information frictions in the form of noise shocks to expectations. We find empirical evidence in favor of DE. In comparison with the RE model, variance decomposition and parameter estimates indicate that the DE model relies significantly less on noise shocks when explaining errors in expectations. As a result, DE offer an improved fit of the interest rate rule. Moreover, the DE model relies more on internal propagation mechanisms than on exogenous shocks to account for the dynamics of price and wage inflation in the data.

A recurrent and novel theme in our paper is that when agents have diagnostic

beliefs about endogenous variables, instead of exogenous processes, new behavioral insights emerge. Endogenous extrapolation, as highlighted throughout our applications, has remarkable economic implications. For instance, when an adverse weather event damages current inventories of a commodity, suppliers become optimistic about future prices in anticipation of a lower future commodity supply. Under DE, suppliers extrapolate the change in inventories, over-investing in the commodity. At a later stage, there is a reversal. Over-investment generates disappointment, and the commodity price is unexpectedly depressed. Similarly, when a taste shock hits, a consumer increases current consumption. Under habit formation, the consumer also anticipates higher consumption in the future. Due to DE, this anticipation is magnified: the consumer forms excessively optimistic beliefs about future consumption, ultimately pushing them to overreact to the taste shock. The paper illustrates these implications with the help of a number of examples.

In order to capture endogenous extrapolation, throughout the paper we will use the property that, when forecasting a variable, say y_{t+1} , where $y_{t+1} = \bar{y}_t + u_{t+1}$ and \bar{y}_t is predetermined, the DE of y_{t+1} is not equal to \bar{y}_t plus the DE of u_{t+1} : $\mathbb{E}_t^\theta[y_{t+1}] \neq \bar{y}_t + \mathbb{E}_t^\theta[u_{t+1}]$ where \mathbb{E}_t^θ is the DE operator, and $\theta > 0$ is a diagnosticity parameter. The representativeness heuristic implies that innovations to predetermined variables produce a form of cue-dependence. These innovations are, in fact, extrapolated into the future, distorting beliefs about future states. We provide intuition for this mechanism in Section 2. There, we also expand on the psychological underpinning of this property by making a connection to recent work on the functioning of human memory (Gennaioli and Shleifer 2010; Kahana 2012; Bordalo, Conlon, Gennaioli, Kwon, and Shleifer 2023).

Related Literature. The paper is primarily related to the emerging literature on DE. See Gennaioli and Shleifer (2018) and Bordalo, Gennaioli, and Shleifer (2022) for a review. Maxted (2022) and Bordalo, Gennaioli, Shleifer, and Terry (2021) incorporate DE in macro-finance frameworks. Maxted (2022) shows that incorporating DE into a macro-finance framework can reproduce several facts surrounding financial crises (see also Krishnamurthy and Li 2021). Bordalo, Gennaioli, Shleifer, and Terry (2021) show that DE can quantitatively generate countercyclical credit spreads in a heterogeneous firms business-cycle model. D’Arienzo (2020) investigates the ability of DE to reconcile the overreaction of expectations of long rates relative to the expectations of short rates to news in bond markets. Ma, Ropele, Sraer, and Thesmar (2020) quantify the costs of managerial biases. We complement these efforts by providing a general treatment of DE in linear macroeconomic models. In particular, we show how incorporating DE

into NK models (Woodford 2003; Galí 2015) delivers rich new insights and significantly improves the fit to the data.

In parallel and complementary work, Bianchi, Ilut, and Saijo (2022) also investigate applications of DE in linear models. Although their work, like ours, is comprehensive, the main focus of their paper is distant memory, the notion that agents' reference distribution looks back more than one period. In such settings, the law of iterated expectations fails, and therefore the model with distant memory is time inconsistent. Our paper focuses exclusively on linear settings with time consistency, and shows that this baseline setup offers a number of insights useful for the NK literature. We outline, in detail, the steps from the exact equilibrium conditions to the loglinear approximation of medium-scale models. Our main empirical focus is evaluating the role of diagnosticity in a rich medium-scale DSGE model with news shocks and information frictions.

Our paper also speaks to the literature proposing deviations from the full-information rational expectations (FIRE) hypothesis. See, for example, Evans and Honkapohja (2001), Mankiw and Reis (2002), Coibion and Gorodnichenko (2015a), Eusepi and Preston (2018), Angeletos, Huo, and Sastry (2020), Bordalo, Gennaioli, Ma, and Shleifer (2020), Kohlhas and Walther (2021), among others. Angeletos, Huo, and Sastry (2020) document delayed overreaction of beliefs in response to business cycle shocks. Bordalo, Gennaioli, Ma, and Shleifer (2020) propose a model of DE with dispersed information to study underreaction and overreaction in survey forecasts. See also Ma, Ropele, Sraer, and Thesmar (2020) and Afrouzi, Kwon, Landier, Ma, and Thesmar (2022). In a related vein, our estimated DSGE model builds on work exploring business cycle models where agents receive advance information about future productivity that is subject to an information friction (Blanchard, L'Huillier, and Lorenzoni 2013; Chahrour and Jurado 2018).

Our paper fits into the macroeconomics literature that models departures from rational expectations with various behavioral assumptions. Some of the recent applications have focused on resolving puzzles in New Keynesian models by introducing behavioral assumptions. Angeletos and Lian (2018), Farhi and Werning (2019), Gabaix (2020), and Garcia-Schmidt and Woodford (2019) are some of the papers that propose departures from rational expectations to attenuate the strength of forward guidance. Iovino and Sergeyev (2021) study the effectiveness of central bank balance sheet policies with level- k thinking. Bianchi-Vimercati, Eichenbaum, and Guerreiro (2022) study the effectiveness of fiscal policy at the zero lower bound in a model with level- k thinking. Angeletos, Huo, and Sastry (2020, Sec. 6.4) argue that these leading departures from

rational expectations exhibit a form of under-extrapolation. In contrast, DE allow beliefs to generate overreaction and systematic reversals as we demonstrate. Farhi and Werning (2020) study the role of monetary policy as a macro-prudential tool when agents form extrapolative expectations.

Paper Organization. The paper is organized as follows. Section 2 offers an example based on the classic demand and supply model by Muth (1961) to illustrate how DE generate endogenous extrapolation, even with i.i.d. shocks. Section 3 presents a general formulation and solution method for linear dynamic DE models, and offers two examples. Section 4 presents the analytical results from a 3-equation NK model. Section 5 presents the empirical evaluation of diagnostic expectations in a medium-scale DSGE model. Section 6 concludes. The Appendix provides supplementary materials and collects all the proofs.

2 Diagnostic Expectations on Endogenous Variables: A Simple Demand and Supply Example

The goal of this section is to illustrate the novel propagation mechanism offered by diagnostic expectations in the context of dynamic models featuring endogenous state variables. For the purposes of providing intuition, let us reconsider one of the examples given in the introduction. Suppose that an adverse weather event damages current inventories of a commodity. Under DE, commodity suppliers extrapolate the effects of the surprise decline in inventories to excessively low future supply, and hence high prices. As a result, they over-invest in the commodity. Ex post, an excessive amount of the commodity breeds disappointment and depressed price dynamics. This is the type of behavior that the models in this paper capture.

In order to illustrate this mechanism, we use the classic commodity market model suggested by Muth (1961), with the addition of imperfect commodity storage leading to partial depreciation. Specifically, the model is the following.² There is an isolated market for a commodity. The commodity demand at time t , Q_t^d , is a downward-sloping function of the price P_t (model variables are denoted in deviation from steady state):

$$Q_t^d = -\beta P_t, \quad \beta > 0 \tag{1}$$

The supply side is modeled with a time-to-build assumption. Suppliers invest, one

²See Muth (1961), Section 3, pp. 317-22.

period in advance, as a function of their expectations of the price next period:

$$I_t = \gamma \mathbb{E}_t^\theta [P_{t+1}], \quad \gamma > 0 \quad (2)$$

where I_t is the quantity invested, \mathbb{E}_t^θ is the DE operator, and $\theta > 0$ is a diagnosticity parameter. Supply at time $t + 1$, Q_{t+1}^s , is given by

$$Q_{t+1}^s = \bar{Q}_t + \epsilon_{t+1} \quad (3)$$

where \bar{Q}_t are inventories at t , given by

$$\bar{Q}_t = I_t + (1 - \delta)Q_t \quad (4)$$

By (4), the predetermined supply of the commodity, or inventory, is equal to the quantity invested at time t , plus the remaining fraction of quantity at t that can be stored away for the next period $t+1$. This stored quantity depreciates at rate $\delta \in (0, 1)$. By (3), the quantity actually supplied is the predetermined amount subject to a shock ϵ_{t+1} , which can be thought as weather events, or other random variation in yields. Whereas Muth assumed that the shock is persistent, we assume instead that ϵ_{t+1} is i.i.d. $N(0, \sigma_\epsilon^2)$, which allows us to focus on the amplification through the endogenous state \bar{Q}_t .³ The market clearing condition is: $Q_t^s = Q_t^d = Q_t$, which implies $P_t = -\frac{1}{\beta}Q_t$.

To help intuition, we focus on the equilibrium effects of a contemporaneous negative shock $\epsilon_t < 0$. This shock reduces the supply of the commodity Q_t , thereby reducing next period inventories \bar{Q}_t . Consider the implication for expected future prices. By the equilibrium condition, we have that $\mathbb{E}_t^\theta [P_{t+1}] = -\frac{1}{\beta} \mathbb{E}_t^\theta [Q_{t+1}]$. A low expected future supply of the commodity implies a high expected future price. Price expectations then determine, according to (2), current investment and hence inventories \bar{Q}_t as a fixed point.

Evidently, then, expectation formation is crucial to determine how the market reacts to the shock $\epsilon_t < 0$. In order to solve for diagnostic expectations, we apply the BGS formula and write $\mathbb{E}_t^\theta [Q_{t+1}] = \mathbb{E}_t [Q_{t+1}] + \theta (\mathbb{E}_t [Q_{t+1}] - \mathbb{E}_{t-1} [Q_{t+1}])$. By (3), we obtain:

$$\mathbb{E}_t^\theta [Q_{t+1}] = \mathbb{E}_t [\bar{Q}_t + \epsilon_{t+1}] + \theta (\mathbb{E}_t [\bar{Q}_t + \epsilon_{t+1}] - \mathbb{E}_{t-1} [\bar{Q}_t + \epsilon_{t+1}]) \quad (5)$$

³The reason the predetermined variable is instrumental to generate amplification via diagnosticity is that it guarantees persistence, even with i.i.d. shocks. Of course, in more general formulations, there is additional amplification because exogenous shocks can themselves be persistent, as in BGS. But, in this section, we focus on the stark i.i.d. case.

which, in turn, implies

$$\mathbb{E}_t^\theta[Q_{t+1}] = \bar{Q}_t + \theta (\bar{Q}_t - \mathbb{E}_{t-1}[\bar{Q}_t]) \quad (6)$$

Diagnosticity implies that a shock affecting the predetermined variable \bar{Q}_t today shapes agents' forecast for an uncertain future. According to (2), when $\epsilon_t < 0$, investment I_t will increase due to two distinct channels. By the first term in (6), the fall in \bar{Q}_t pushes I_t up. This channel is present even under RE. By the second term in (6), investment will increase further due to extrapolation of lower-than-expected current inventories into the future ($\bar{Q}_t - \mathbb{E}_{t-1}[\bar{Q}_t] < 0$), which has a positive effect on I_t . The magnitude of this second channel is governed by the diagnosticity parameter θ .

Note that equation (5) implies that the predetermined endogenous variable \bar{Q}_t is not taken out of the diagnostic expectations operator, mainly $\mathbb{E}_t^\theta[Q_{t+1}] \neq \bar{Q}_t + \mathbb{E}_t^\theta[\epsilon_{t+1}]$. This property is critical for amplification, and is founded on the cognitive influence of associative memory on beliefs. Seeing $\epsilon_t < 0$ and hence lower-than-expected inventories \bar{Q}_t makes the investor selectively retrieve low Q_{t+1} in the future, over and above the rational link between Q_{t+1} and \bar{Q}_t . Specifically, suppose that the representative supplier has stored an exogenous baseline or reference level of the inventory stock \bar{Q}_t^R in her memory. Denote by Q_{t+1}^M a supplier's belief about future supply. This belief depends on the current endogenous inventory, which acts as a memory cue. Let us denote such cue by \bar{Q}_t^M . We then have $Q_{t+1}^M = \bar{Q}_t^M + \epsilon_{t+1}^M$, where ϵ_{t+1}^M is a given resolution of future uncertainty. By the representativeness heuristic, when thinking about Q_{t+1}^M based on the cue \bar{Q}_t^M , the supplier disproportionately retrieves future outcomes that are more likely compared to $Q_{t+1}^R = \bar{Q}_t^R + \epsilon_{t+1}^M$. Thus, the difference $\bar{Q}_t^M - \bar{Q}_t^R$ leads to a behavioral distortion that feeds into beliefs about the future supply and hence the price, ultimately affecting the action I_t . Notice that $\bar{Q}_t^M - \bar{Q}_t^R < 0$ when $\epsilon_t < 0$. In equilibrium, the cue \bar{Q}_t^M coincides with the endogenously determined quantity \bar{Q}_t , and the exogenous reference with its average value under past conditions:

$$\bar{Q}_t^M = \bar{Q}_t \quad (7)$$

$$\bar{Q}_t^R = \mathbb{E}_{t-1}[\bar{Q}_t] \quad (8)$$

This mechanism is consistent with findings from psychology and behavioral economics, which document evidence of a wide range of distortions and inconsistencies in the formation of beliefs under uncertainty,⁴ and with recent work that offers common

⁴See Tversky and Koehler (1994), Gonzalez and Wu (1999), Enke and Graeber (2023), Dietrich, Knotek, Myrseth, Rich, Schoenle, and Weber (2022), among others.

memory-based foundations for these anomalies (Gennaioli and Shleifer 2010; Kahana 2012, Ch. 4; Bordalo, Conlon, Gennaioli, Kwon, and Shleifer 2023; Enke, Schwerter, and Zimmermann 2020). In fact, by (6), notice that

$$\mathbb{E}_t^\theta[Q_{t+1}] \neq \bar{Q}_t + \mathbb{E}_t^\theta[\epsilon_{t+1}] \quad (9)$$

This distortion holds the key to amplification through endogenous variables, and it is triggered even in the case of i.i.d. exogenous processes.

We now show that here memory mechanisms triggered by adjustments in endogenous variables amplify the actions of forward looking agents and create persistence with i.i.d. shocks. The equilibrium consistency restrictions (7) and (8) lead to the explicit solution for the endogenous variables.⁵ Equilibrium investment is given by:

$$I_t = -\frac{\gamma}{\beta + \gamma}(1 - \delta)Q_t - \frac{\beta}{\beta + \gamma} \frac{\theta\gamma(1 - \delta)}{\beta + \gamma(1 + \theta)}\epsilon_t \quad (10)$$

The dynamics of the price are given by

$$P_t = \frac{\beta}{\beta + \gamma}(1 - \delta)P_{t-1} - \frac{1}{\beta}\epsilon_t + \frac{1}{\beta + \gamma} \frac{\theta\gamma(1 - \delta)}{\beta + \gamma(1 + \theta)}\epsilon_{t-1} \quad (11)$$

These expressions lead to three insights. First, in the absence of storage opportunities ($\delta = 1$), investment is fixed at steady state ($I_t = 0$). The reason is that, with i.i.d. shocks and no storage, the forecast of the future price is simply given by its long-run mean. Second, for $\delta < 1$, investment moves in the *opposite* direction of the shock ϵ_t . As discussed above, there are two channels. There is a direct “rational” effect via the supply Q_t , captured by the first term on the right-hand side of (10). Furthermore, there is an extrapolative effect of the current shock ϵ_t , implied by DE, and captured by the second term. The latter is shut down at the RE benchmark $\theta = 0$.⁶ Third, price dynamics follow an ARMA(1,1) process. As in a rational world, $\theta = 0$, the price is positively correlated to the past price, but it is hit negatively by the contemporaneous weather shock (a negative shock $\epsilon_t < 0$ increasing the price P_t). Adding diagnosticity $\theta > 0$, though, adds a key new effect: a systematic price *reversal* that entails a depressed price P_{t+1} , after a bad shock ϵ_t . Indeed, equation (11), one period forward,

⁵This solution can be obtained by a guess and verify procedure.

⁶Notice that, both under RE and DE, the *endogenous* adjustment of I_t goes in the opposite direction of the *exogenous* shock on Q_t . Under DE, the extrapolation changes the magnitude of the response of I_t , making it larger than under RE. The total effect on inventories \bar{Q}_t preserves the direction of the initial impulse of the shock, both under RE and DE. (This can be checked using (11) and solving explicitly for \bar{Q}_t .)

Figure 1: Implications of a Negative Commodity Supply Shock

Notes: The panels present the responses of investment I_t and the price P_t to a one unit negative shock ϵ_t . The solid and dashed lines depict the responses under DE ($\theta = 5$ and $\theta = 1$), whereas the dotted lines depict responses under RE.

is:

$$P_{t+1} = \frac{\beta}{\beta + \gamma}(1 - \delta)P_t - \frac{1}{\beta}\epsilon_{t+1} + \frac{1}{\beta + \gamma} \frac{\theta\gamma(1 - \delta)}{\beta + \gamma(1 + \theta)}\epsilon_t \quad (12)$$

The third term on the right-hand side of (12) tells us that the shock $\epsilon_t < 0$ makes P_{t+1} go down compared to RE. To understand this price reversal, consider the investment equation (10) and the extrapolative effect due to diagnosticity. Because of over-investment when a negative shock $\epsilon_t < 0$ hits, the market is glutted with an excessively high quantity of the commodity. This reversal is neglected by diagnostic agents. This also implies that the rosy price expectations of diagnostic suppliers are disappointed, with the price falling below the prevailing price in the RE economy. The discrepancy from time t expectations is systematic and predictable, since it depends purely on the past shock. Also, due to the AR component of the equilibrium price process (12) when $\delta < 1$, this reversal is persistent.

We illustrate these dynamics in Figure 1.⁷ Following the negative shock, both investment and the price rise. However, under DE, investment overreacts on impact, and then rapidly reverts (already at $t = 2$) to a level that is below the RE response. This ‘overreaction-and-systematic-reversal’ pattern is more dramatic the higher the value of θ . Due to over-investment, the price is depressed (below the RE benchmark) from $t = 2$ onwards. The economy gradually returns to steady state as inventories recover from the shock (not plotted).

As in this example, throughout the paper we use the property that innovations to predetermined variables generate cues that distort the forecasts of future states.

We label this property *endogenous extrapolation*. As just illustrated, this property is

⁷For illustration, we set $\theta = 1$ or $\theta = 5$, $\delta = 0.10$, and $\gamma = \beta = 1$.

important and can give rise to excess volatility and reversals. Given that endogenous states are ubiquitous in DSGEs models, due to the presence of predetermined variables such as capital, inflation, or consumption habits, this property of DE is attractive to obtain amplification in these models.

3 Solution Method

We present a solution method for a general class of linear models. Agents use diagnostic expectations to form beliefs about the evolution of all variables, exogenous and endogenous. Our strategy consists in obtaining a rational expectations (RE) representation of the diagnostic expectations (DE) model. Based on this step, the model can be solved using standard techniques.

3.1 General Formulation and Rational Expectations Representation

3.1.1 Exogenous Processes

We start by specifying the exogenous drivers of the economy. Exogenous variables are stacked in a $(n \times 1)$ vector \mathbf{x}_t that is assumed to follow the multivariate AR(1) stochastic process

$$\mathbf{x}_t = \mathbf{A}\mathbf{x}_{t-1} + \mathbf{v}_t \quad (13)$$

where \mathbf{v}_t is a $(k \times 1)$ vector of Normal and orthogonal exogenous shocks, $\mathbf{v}_t \sim N(0, \Sigma_{\mathbf{v}})$, and \mathbf{A} is a diagonal matrix of persistence parameters. Since vector \mathbf{x}_{t+1} follows a multivariate normal distribution, we can write its true (or non-distorted) pdf as $f(\mathbf{x}_{t+1}|\mathbf{x}_t) \propto \varphi((\mathbf{x}_{t+1} - \mathbf{A}\mathbf{x}_t)' \Sigma_{\mathbf{v}}^{-1} (\mathbf{x}_{t+1} - \mathbf{A}\mathbf{x}_t))$, where $\varphi(x)$ is the density of a standard normal distribution, $\varphi(x) = \frac{1}{\sqrt{2\pi}} e^{-\frac{1}{2}x^2}$.

3.1.2 Diagnostic Expectations

Extending the approach by Bordalo, Gennaioli, and Shleifer (2018) (henceforth BGS), the multivariate diagnostic distribution of \mathbf{x}_{t+1} is defined as

$$f_t^\theta(\mathbf{x}_{t+1}) = f(\mathbf{x}_{t+1}|G_t) \cdot \left[\frac{f(\mathbf{x}_{t+1}|G_t)}{f(\mathbf{x}_{t+1}|-G_t)} \right]^\theta \cdot C \quad (14)$$

where G_t and $-G_t$ are conditioning events. G_t encodes current conditions: $G_t \equiv \{\mathbf{x}_t = \check{\mathbf{x}}_t\}$, where $\check{\mathbf{x}}_t$ denotes the realization of \mathbf{x}_t . $-G_t$ encodes a reference group (i.e.

a reference event), that is used to compute the reference distribution $f(\mathbf{x}_{t+1}|-G_t)$. Due to the representativeness heuristic, agents overweight the last realization of \mathbf{x}_t (relative to the reference group) when forming beliefs about the future realization of \mathbf{x}_{t+1} . The likelihood ratio $f(\mathbf{x}_{t+1}|G_t)/f(\mathbf{x}_{t+1}|-G_t)$ distorts beliefs to a degree governed by the diagnosticity parameter $\theta \geq 0$. C is a constant ensuring that $f_t^\theta(\mathbf{x}_{t+1})$ integrates to 1.

Following BGS, we impose that, in the presence of uncertainty about \mathbf{x}_{t+1} , the reference event $-G_t$ carries “no news” at time t (henceforth no-news assumption or NNA).

Assumption 1 (Multivariate No-News Assumption)

$$f(\mathbf{x}_{t+1}|-G_t) = f(\mathbf{x}_{t+1}|\mathbf{x}_t = \mathbf{A}\check{\mathbf{x}}_{t-1}) \quad (15)$$

We make Assumption 1 throughout the paper. To understand the meaning of this assumption, consider an agent forming beliefs about future \mathbf{x}_{t+1} . Under the NNA, these beliefs are formed conditional on the event that the random variable \mathbf{x}_t , conditional on the past realization $\check{\mathbf{x}}_{t-1}$, is what it was expected to be, so $\mathbf{v}_t = \mathbb{E}[\mathbf{v}_t] = 0$, which is equivalent to $\mathbf{x}_t = \mathbf{A}\check{\mathbf{x}}_{t-1}$. The diagnostic distribution is thus written as

$$f_t^\theta(\mathbf{x}_{t+1}) = f(\mathbf{x}_{t+1}|\mathbf{x}_t = \check{\mathbf{x}}_t) \cdot \left[\frac{f(\mathbf{x}_{t+1}|\mathbf{x}_t = \check{\mathbf{x}}_t)}{f(\mathbf{x}_{t+1}|\mathbf{x}_t = \mathbf{A}\check{\mathbf{x}}_{t-1})} \right]^\theta \cdot C \quad (16)$$

Notice that the distribution (16) is conditional on two elements: first, it is conditional on the current realization of \mathbf{x}_t , written $\check{\mathbf{x}}_t$, because this enters the true distribution of \mathbf{x}_{t+1} ; second, it is conditional on the reference event $-G_t \equiv \{\mathbf{x}_t = \mathbf{A}\check{\mathbf{x}}_{t-1}\}$, which depends on the realization at $t-1$, $\check{\mathbf{x}}_{t-1}$.

Extending the definition of BGS to the multivariate normal vector \mathbf{x}_{t+1} , the DE is the expectation, element by element, under the density (16). We write this expectation as $\mathbb{E}_t^\theta[\mathbf{x}_{t+1}]$.⁸ Using a multivariate version of Proposition 1 in BGS, we obtain the formula⁹

$$\mathbb{E}_t^\theta[\mathbf{x}_{t+1}] = \mathbb{E}_t[\mathbf{x}_{t+1}] + \theta(\mathbb{E}_t[\mathbf{x}_{t+1}] - \mathbb{E}_{t-1}[\mathbf{x}_{t+1}]) \quad (17)$$

⁸The diagnostic distribution depends on two separate information sets, G_t and G_{-t} , drawing information available at dates t and $t-1$. So, one could denote it by $\mathbb{E}_{t,t-1}^\theta$. However, to avoid confusion, we prefer to stick to the notation used in BGS and the surrounding literature. Similarly, when denoting the RE operator \mathbb{E}_t , the subindex indicates the date at which the expectation is taken (in which case it coincides with the information set’s date.)

⁹See Lemma 2 in the appendix.

3.1.3 Stochastic Difference Equation

The class of forward-looking models we analyze is written as a stochastic difference equation. Uncertainty is modeled under the diagnostic distribution (16). Let \mathbf{y}_t denote a $(m \times 1)$ vector of endogenous variables (including jump variables and states) and \mathbf{x}_t , as above, denote the $(n \times 1)$ vector of exogenous states. The model is:

$$\mathbb{E}_t^\theta[\mathbf{F}\mathbf{y}_{t+1} + \mathbf{G}_1\mathbf{y}_t + \mathbf{M}\mathbf{x}_{t+1} + \mathbf{N}_1\mathbf{x}_t] + \mathbf{G}_2\mathbf{y}_t + \mathbf{H}\mathbf{y}_{t-1} + \mathbf{N}_2\mathbf{x}_t = 0 \quad (18)$$

where \mathbf{F} , \mathbf{G}_1 , \mathbf{G}_2 , \mathbf{M} , \mathbf{N}_1 , \mathbf{N}_2 , and \mathbf{H} , are matrices of parameters. \mathbf{F} , \mathbf{G}_1 , \mathbf{G}_2 , and \mathbf{H} are $(m \times m)$ matrices, \mathbf{N}_1 and \mathbf{N}_2 are $(m \times n)$ matrices. This diagnostic expectation is taken over the diagnostic density of $\mathbf{F}\mathbf{y}_{t+1} + \mathbf{G}_1\mathbf{y}_t + \mathbf{M}\mathbf{x}_{t+1} + \mathbf{N}_1\mathbf{x}_t$. For generality, in equation (18), we specify current variables both inside the diagnostic expectations operator in linear combination with future variables (e.g. $\mathbf{N}_1\mathbf{x}_t$) as well as outside the expectations operator (e.g. $\mathbf{N}_2\mathbf{x}_t$).¹⁰ Such expressions can arise due to the presence of exogenous persistent states \mathbf{x}_t or predetermined variables \mathbf{y}_t .

3.1.4 Solution Procedure

The remaining steps are as follows. First, postulate a form for the solution. Second, determine how to handle the diagnostic expectation $\mathbb{E}_t^\theta[\mathbf{F}\mathbf{y}_{t+1} + \mathbf{G}_1\mathbf{y}_t + \mathbf{M}\mathbf{x}_{t+1} + \mathbf{N}_1\mathbf{x}_t]$, which is a linear combination of endogenous and exogenous variables, some of which are future, and some of which are current (known at time t). Third, obtain a rational expectations representation of the model. Fourth, solve for the model expressed in terms of rational expectations using standard tools (as the method of undetermined coefficients, for instance).

Form of the Solution. We look for a solution of the form

$$\mathbf{y}_t = \mathbf{P}\mathbf{y}_{t-1} + \mathbf{Q}\mathbf{x}_t + \mathbf{R}\mathbf{v}_t \quad (19)$$

We make this guess based on the behavioral properties afforded by DE. In the context of RE models, the correct conjecture is of the form $\mathbf{y}_t = \mathbf{P}\mathbf{y}_{t-1} + \mathbf{Q}\mathbf{x}_t$. As shown by BGS, DE generate overreaction in the context of exogenous processes. We allow for this possibility in the context of the endogenous dynamics of \mathbf{y}_t using the extra term $\mathbf{R}\mathbf{v}_t$.

¹⁰After loglinearization we will encounter expressions of this form. Throughout the paper we present a few examples to make this point concrete.

Diagnostic Expectation of Linear Combinations of Endogenous and Exogenous Variables. Under (19), \mathbf{y}_{t+1} follows a multivariate normal distribution. Since the vector of exogenous drivers \mathbf{x}_{t+1} also follows a multivariate normal distribution, we know that the linear combination $\mathbf{F}\mathbf{y}_{t+1} + \mathbf{G}_1\mathbf{y}_t + \mathbf{M}\mathbf{x}_{t+1} + \mathbf{N}_1\mathbf{x}_t$ is *also* distributed following a multivariate normal density. This Gaussian property is the key to the solution to the model. Using (17), it allows us to express the diagnostic expectation $\mathbb{E}_t^\theta[\mathbf{F}\mathbf{y}_{t+1} + \mathbf{G}_1\mathbf{y}_t + \mathbf{M}\mathbf{x}_{t+1} + \mathbf{N}_1\mathbf{x}_t]$ in terms of the RE operator \mathbb{E}_t . Indeed, the expression for the DE present in model (18) can be expressed as:

$$\begin{aligned}\mathbb{E}_t^\theta[\mathbf{F}\mathbf{y}_{t+1} + \mathbf{G}_1\mathbf{y}_t + \mathbf{M}\mathbf{x}_{t+1} + \mathbf{N}_1\mathbf{x}_t] &= \mathbb{E}_t[\mathbf{F}\mathbf{y}_{t+1} + \mathbf{G}_1\mathbf{y}_t + \mathbf{M}\mathbf{x}_{t+1} + \mathbf{N}_1\mathbf{x}_t] \\ &\quad + \theta(\mathbb{E}_t[\mathbf{F}\mathbf{y}_{t+1} + \mathbf{G}_1\mathbf{y}_t + \mathbf{M}\mathbf{x}_{t+1} + \mathbf{N}_1\mathbf{x}_t] \\ &\quad - \mathbb{E}_{t-1}[\mathbf{F}\mathbf{y}_{t+1} + \mathbf{G}_1\mathbf{y}_t + \mathbf{M}\mathbf{x}_{t+1} + \mathbf{N}_1\mathbf{x}_t])\end{aligned}\quad (20)$$

We are now in a position to obtain the representation of the model in terms of rational expectations.

Proposition 1 (Multivariate Rational Expectations Representation) *Under the multivariate NNA, model (18) admits the following RE representation:*

$$\begin{aligned}\mathbf{F}\mathbb{E}_t[\mathbf{y}_{t+1}] + \mathbf{G}\mathbf{y}_t + \mathbf{H}\mathbf{y}_{t-1} + \mathbf{M}\mathbb{E}_t[\mathbf{x}_{t+1}] + \mathbf{N}\mathbf{x}_t \\ + \mathbf{F}\theta(\mathbb{E}_t[\mathbf{y}_{t+1}] - \mathbb{E}_{t-1}[\mathbf{y}_{t+1}]) \\ + \mathbf{M}\theta(\mathbb{E}_t[\mathbf{x}_{t+1}] - \mathbb{E}_{t-1}[\mathbf{x}_{t+1}]) \\ + \mathbf{G}_1\theta(\mathbf{y}_t - \mathbb{E}_{t-1}[\mathbf{y}_t]) \\ + \mathbf{N}_1\theta(\mathbf{x}_t - \mathbb{E}_{t-1}[\mathbf{x}_t]) = 0\end{aligned}\quad (21)$$

where $\mathbf{G} = \mathbf{G}_1 + \mathbf{G}_2$ and $\mathbf{N} = \mathbf{N}_1 + \mathbf{N}_2$. Moreover, this representation is unique.

The proof of this result is based on equality (20), together with the additivity property of the RE expectations operator.

Solution. Armed with this representation, we verify that equation (19) indeed constitutes a solution. See the appendix for the details.

Belief Distortions and Predetermined Variables. Notice that a key step in arriving at the RE representation has the feature that we already discussed in Section 2. The vectors of predetermined variables \mathbf{x}_t and \mathbf{y}_t undergo a diagnostic transformation in equation (20), since expectations are taken over a linear combination involving future

variables. Innovations to the current states (exogenous or endogenous) give rise to a cue-dependence that distorts expectations. Hence, current variables cannot be taken out of the DE operator in (18).

This does not mean that if the agent were to be asked, at date t , about their expectation of \mathbf{x}_t or \mathbf{y}_t in isolation, they would respond something different than \mathbf{x}_t or \mathbf{y}_t . Instead, when the expectation of \mathbf{x}_t or \mathbf{y}_t is evaluated in linear combination with future variables, the presence of uncertainty about future outcomes activates diagnosticity in the mind of the agent.

The fact that uncertainty activates diagnosticity could result in behavioral inconsistencies in the limiting case when uncertainty disappears. For example, $\mathbf{y}_t = \mathbb{E}_t^\theta[\mathbf{y}_t] = \mathbb{E}_t^\theta[\mathbf{y}_t + \mathbf{y}_{t+1} - \mathbf{y}_{t+1}]$, even though the last term evaluates expectations over a linear combination involving future variables.¹¹ In such a limiting case, the agent does not overweight, in the true distribution of \mathbf{y}_t , any specific outcomes that could lead to a distortion. In reality, of course, matters are more subtle. Because memory is limited (Kahana 2012), even if a variable is predetermined and the agent has observed its realization, when trying to recall its value, the agent can make mistakes that depend on the selectivity of memory. With limited memory, beliefs may be distorted not only about future outcomes, but also about past ones. For instance, in the example of Section 2, where agents form beliefs about $Q_{t+1} = \bar{Q}_t + \epsilon_{t+1}$, there might be a behavioral instability depending on the framing of the question. When asked about their beliefs about \bar{Q}_t , an agent may have no trouble stating an unbiased response. However, when asked about their beliefs about Q_{t+1} , the agent may report a number that is inconsistent with reporting \bar{Q}_t in the former question. There is a large body of evidence of inconsistencies of this sort in peoples' expectations. For instance, Dietrich et al. (2022) show how expectations about aggregate inflation are inconsistent with expectations at the good subcategory levels. See also Tversky and Koehler (1994), Enke and Graeber (2023), among others.

3.2 Examples: Endogenous Extrapolation, Stability and Boundedness of the Solution, Loglinearization

In order to economize on technical material, we use two examples to discuss two remaining issues pertaining to the solution method of DSGE models under DE. Example 1 discusses the stability and boundedness properties of the DE solution. Example 2

¹¹Bianchi, Ilut, and Saijo (2022, Appendix D) explain that a researcher needs to verify whether there is residual uncertainty inside the expectations operator or not before computing the expectations.

discusses the loglinearization of DE models.¹² Moreover, these two examples are useful to further illustrate the recurrent theme of how DE generate endogenous extrapolation in models with predetermined variables.

3.2.1 Example 1: Univariate Endogenous State Variable Model

The main purpose of this example is to further illustrate the endogenous extrapolation property introduced in Section 2. When DE are taken over exogenous variables, there is no extrapolation if shocks are i.i.d. There is in fact an equivalence between RE and DE. To see this, consider an i.i.d. white noise process η_t , and compute $\mathbb{E}_t^\theta[\eta_{t+1}]$. A simple calculation using formula (17) shows that RE and DE are equivalent in this case. Instead, in the context of DE over endogenous variables, state variables can activate extrapolation *even* when shocks are i.i.d.. This is due to the presence of predetermined variables. Modeling diagnostic expectations on endogenous variables offers a novel and internal propagation mechanism for DSGE models.

Consider the following model:

$$y_t = a\mathbb{E}_t^\theta[y_{t+1}] + cy_{t-1} + \varepsilon_t \quad (22)$$

where $|a + c| < 1$ and ε_t is white noise.¹³

The solution of the RE model ($\theta = 0$) can be derived analytically using the minimum state variable solution method:

$$y_t = \phi_1 y_{t-1} + \frac{1}{1 - a\phi_1} \varepsilon_t \quad (23)$$

where $\phi_1 \equiv \frac{1 - \sqrt{1 - 4ac}}{2a}$.¹⁴ Under DE, the minimum state variable solution is given by

$$y_t = \phi_1 y_{t-1} + \frac{1}{1 - (1 + \theta)a\phi_1} \varepsilon_t \quad (24)$$

Notice from equation (24) that computing the DE over the endogenous variable y_{t+1} delivers extrapolation and amplification, even though the exogenous process is i.i.d. To see this, notice that since $1 - a\phi_1 > 0$, for small enough θ (more on this below), a positive shock ε_t generates an overreaction of y_t .

¹²The appendix presents a thorough technical discussion of these aspects.

¹³This equation can be microfounded with a standard intertemporal consumer problem subject to external habits in consumption. ε_t can be interpreted as a taste shock.

¹⁴Specifically, using the method of undetermined coefficients, we get the following requirement: $\phi_1 = a\phi_1^2 + c$. Imposing that $\phi_1 \rightarrow 0$ as $c \rightarrow 0$, we arrive at the solution. $|a + c| < 1$ ensures that the model is stable in the sense of Proposition 5 and that the RE solution is bounded.

Figure 2: Amplification in the Univariate Model

To get intuition, consider Figure 2. On the (y_{t+1}, y_t) plane, we plot the form of the solution, $y_{t+1} = \phi_1 y_t$ (dotted line) and the forward-looking reaction functions $y_t = a\mathbb{E}_t^\theta[y_{t+1}] + \varepsilon_t$ (solid line) and $y_t = a\mathbb{E}_t[y_{t+1}] + \varepsilon_t$ (dashed line). We assume the economy is in steady state before the shock, and thus $y_{t-1} = 0$. Under RE, the reaction function collapses to $y_t = ay_{t+1} + \varepsilon_t$. Under DE, the reaction function is, instead, $y_t = a(1 + \theta)y_{t+1} + \varepsilon_t$. The intersection of the dotted line with either reaction function (RE or DE) gives the solution. Because of extrapolation, the reaction function is steeper under DE, signifying the higher expectation of y_{t+1} in the mind of the agent. This extrapolation is the source of amplification at date t .¹⁵

Finally, both the DE and RE solutions are dynamically stable since $\phi_1 < 1$. In fact, this is a general property. The stability conditions are identical for both models. Furthermore, the solution to the RE model is bounded since $1 - a\phi_1 > 0$. However, notice that the denominator in (24), $1 - (1 + \theta)a\phi_1$, can be zero. Therefore, the DE solution becomes unbounded as θ approaches $\frac{1}{a\phi_1} - 1$, despite the existence of a bounded RE solution. In all our applications, we verify that the values of θ that lead to unboundedness are always fairly large and away from any admissible range.

3.2.2 Example 2: Nominal Euler Equation

Consider the following Euler equation of a nominal economy:

$$\frac{u'(C_t)}{P_t} = \beta(1 + i_t)\mathbb{E}_t^\theta \left[\frac{u'(C_{t+1})}{P_{t+1}} \right] \quad (25)$$

¹⁵In other words: Given the solution $y_{t+1} = \phi_1 y_t + 1/(1 - (1 + \theta)a\phi_1)\varepsilon_{t+1}$, computing $\mathbb{E}_t^\theta[y_{t+1}]$ delivers $\phi_1(y_t + \theta(y_t - \mathbb{E}_{t-1}[y_t]))$, and so we see that, again, $\mathbb{E}_t^\theta[y_{t+1}] \neq \phi_1 y_t + \mathbb{E}_t^\theta[1/(1 - (1 + \theta)a\phi_1)\varepsilon_{t+1}]$. This is the distortion that generates amplification.

where C_t is consumption, P_t is the price level, i_t is the nominal rate, $u(\cdot) = \log(\cdot)$ is period utility, and β is the discount factor.¹⁶

Loglinearizing (25), we obtain:

$$\hat{c}_t = \mathbb{E}_t^\theta [\hat{c}_{t+1}] - (\hat{i}_t - (\mathbb{E}_t^\theta [\hat{p}_{t+1}] - \hat{p}_t)) \quad (26)$$

where $\{\hat{c}_t, \hat{i}_t, \hat{p}_t\}$ denote loglinear deviations of consumption and the interest rate from their respective steady states, and of the price level from an initial price level, respectively. In order to obtain an expression involving inflation instead of the price level, recognize that the future price level is given by

$$\hat{p}_{t+1} = \hat{p}_t + \hat{\pi}_{t+1} \quad (27)$$

where $\hat{\pi}_{t+1}$ is the inflation rate from t to $t + 1$. Using the BGS formula (17) on \hat{p}_{t+1} and algebraic manipulation delivers the loglinear diagnostic Euler equation¹⁷

$$\hat{c}_t = \mathbb{E}_t^\theta [\hat{c}_{t+1}] - (\hat{i}_t - \mathbb{E}_t^\theta [\hat{\pi}_{t+1}]) + \theta(\hat{\pi}_t - \mathbb{E}_{t-1}[\hat{\pi}_t]) \quad (28)$$

Notice the term $\theta(\hat{\pi}_t - \mathbb{E}_{t-1}[\hat{\pi}_t])$ that enters in the evaluation of the real rate of interest. This term arises due to endogenous extrapolation, whereby the diagnostic agent extrapolates innovations to *current inflation*, impacting beliefs about *future* inflation. The intuition for this distortion is the same as the one given in Section 2, and in the previous example. The presence of the current price level as a predetermined variable in (27) generates endogenous extrapolation, since $\mathbb{E}_t^\theta [\hat{p}_{t+1}] \neq \hat{p}_t + \mathbb{E}_t^\theta [\hat{\pi}_{t+1}]$. When $\hat{\pi}_t - \mathbb{E}_{t-1}[\hat{\pi}_t] > 0$, this channel induces an *expansionary* channel by reducing the subjective real rate computed by diagnostic agents. This effect is present even in the case of i.i.d. shocks, once again underscoring the novelty of computing DE on endogenous variables. We exploit this channel in Section 4 by emphasizing its implications for fiscal policy.¹⁸

¹⁶Section 4 derives this equation from first principles. Following BGS, the diagnostic distribution for non-linear processes is also defined as a distorted likelihood that over-weights states representative of recent news. We provide a formal definition in Appendix C.

¹⁷See Appendix C for the derivation.

¹⁸More generally, this example highlights that predetermined variables cannot be taken in and out of the DE expectation operator in order to obtain the correct loglinear approximation of DSGE models under DE.

3.3 A Practical Guide to the Implementation of Diagnostic Expectations in DSGE Models

We conclude this section with the following summary. A researcher interested in using diagnostic expectations within a DSGE model can take the following steps.

1. Obtain the exact equilibrium conditions of the model. (Section 4 provides an example in the context of a 3-equation NK model, and Section 5 in the context of a medium-scale DSGE model.)
2. Loglinearize the model, being careful not to introduce current variables in and out of the DE operator. (See the appendix for examples.)
3. Obtain the RE representation of the model (Proposition 1).
4. Solve the RE model based on a software package that can handle expectations conditional on previous period's information set (\mathbb{E}_{t-1}).
5. Check that the set of parameter values considered does not cover bifurcation points (Example 1).

4 Analysis Using a New Keynesian Model

In this section, we derive a three-equation New Keynesian model augmented by diagnostic expectations. Our goal is to revisit a number of prominent themes in this context.

4.1 Diagnostic New Keynesian Model

We set up the model from first principles. There are three sets of agents in the economy: households, firms and the government.

4.1.1 Households

Households maximize the following lifetime utility

$$\log C_t - \frac{\omega}{1+\nu} L_t^{1+\nu} + \mathbb{E}_t^\theta \left[\sum_{s=t+1}^{\infty} \beta^{s-t} \left(\log(C_s) - \frac{\omega}{1+\nu} L_s^{1+\nu} \right) \right] \quad (29)$$

where L_t is labor supply, $\nu > 0$ is the inverse of the Frisch elasticity of labor supply, β is the discount factor β , satisfying $0 < \beta < 1$, $\omega > 0$ is a parameter that pins down

the steady-state level of hours. Maximization is subject to a budget constraint:

$$P_t C_t + \frac{B_{t+1}}{(1 + i_t)} = B_t + W_t L_t + D_t + T_t \quad (30)$$

where P_t is the price level, B_{t+1} is the demand of nominal bonds that pay off $1 + i_t$ interest rate in the following period, W_t is the wage, D_t and T_t are dividends from firm-ownership and lump-sum government transfers, respectively.¹⁹

4.1.2 Firms

Monopolistically competitive firms, indexed by $j \in [0, 1]$, produce a differentiated good, $Y_t(j)$. We assume a Dixit-Stiglitz aggregator that aggregates intermediate goods into a final good, Y_t . Intermediate goods' demand is given by $Y_t(j) = \left(\frac{P_t(j)}{P_t}\right)^{-\epsilon_p} Y_t$, where $\epsilon_p > 1$ is the elasticity of substitution, $P_t(j)$ is the price of intermediate good j , and P_t is the price of final good Y_t . Each intermediate good is produced using the technology $Y_t(j) = A_t L_t(j)$, where $\hat{a}_t \equiv \log(A_t)$ is an aggregate TFP process that follows an AR(1) process with persistence coefficient ρ_a :

$$\hat{a}_t = \rho_a \hat{a}_{t-1} + \varepsilon_{a,t} \quad (31)$$

and $\varepsilon_{a,t} \sim iid N(0, \sigma_a^2)$. The firm pays a quadratic adjustment cost $\frac{\psi_p}{2} \left(\frac{P_t(j)}{P_{t-1}(j)} - 1\right)^2 P_t Y_t$, in units of the final good (Rotemberg 1982) to adjust prices. Firms' per period profits are given by $D_t \equiv P_t(j) Y_t(j) - W_t L_t(j) - \frac{\psi_p}{2} \left(\frac{P_t(j)}{P_{t-1}(j)} - 1\right)^2 P_t Y_t$. The firm's profit maximization problem is

$$\max_{P_t(j)} \left\{ P_t(j) Y_t(j) - W_t L_t(j) - \frac{\psi_p}{2} \left(\frac{P_t(j)}{P_{t-1}(j)} - 1\right)^2 P_t Y_t + \mathbb{E}_t^\theta \left[\sum_{s=1}^{\infty} \beta^s Q_{t,t+s} D_{t+s} \right] \right\} \quad (32)$$

where $Q_{t,t+s}$ is the household's nominal stochastic discount factor.

4.1.3 Government

The government sets nominal interest rate with the following rule $1 + i_t = (1 + i_{ss}) \Pi_t^{\phi_\pi} \left(\frac{Y_t}{Y_t^*}\right)^{\phi_x}$, where $Y_t^* = A_t$ is the natural rate allocation, $i_{ss} = \frac{1}{\beta} - 1$ is the steady state nominal interest rate, $\phi_\pi \geq 0$, $\phi_x \geq 0$, and steady state gross inflation

¹⁹The reader may wonder whether DE introduces time inconsistency. This is not the case in the loglinear approximation when the reference distribution is based on $t - 1$. See Bianchi et al. (2022) for an in-depth discussion of cases where DE lead to time inconsistency.

$\Pi = 1$. Total output produced is equal to household consumption expenditure and adjustment costs spent when adjusting prices. We first consider a model where there is no government spending, and nominal bonds are in zero net supply.

4.1.4 Equilibrium

Appendix C presents the equilibrium conditions. In particular, it shows that the household intertemporal first order condition is equation (25). This appendix also goes over the log-linear approximation in detail. The resulting equilibrium is given by the following four equations:

$$\hat{c}_t = \mathbb{E}_t^\theta [\hat{c}_{t+1}] - (\hat{i}_t - (\mathbb{E}_t^\theta [\hat{p}_{t+1}] - \hat{p}_t)) \quad (33)$$

$$\hat{\pi}_t = \beta \mathbb{E}_t^\theta [\hat{\pi}_{t+1}] + \tilde{\kappa}(\hat{c}_t - \hat{a}_t) + \tilde{\kappa}\nu(\hat{y}_t - \hat{a}_t) \quad (34)$$

$$\hat{i}_t = \phi_\pi \hat{\pi}_t + \phi_x(\hat{y}_t - \hat{a}_t) \quad (35)$$

$$\hat{c}_t = \hat{y}_t \quad (36)$$

where $\tilde{\kappa} \equiv \frac{\epsilon_p - 1}{\psi_p}$, \hat{y}_t , \hat{c}_t , \hat{p}_t , \hat{i}_t are the log deviation of output, consumption, the price level, and the nominal interest rate respectively, and $\hat{\pi}_t$ is the log deviation of inflation from the zero-inflation steady state. The shock process is given by:

$$\hat{a}_t = \rho_a \hat{a}_{t-1} + \varepsilon_{a,t} \quad (37)$$

where $\varepsilon_{a,t} \sim i.i.d. N(0, \sigma_a^2)$.

As explain in the context of Example 2 in Section 3, equation (33) can be written as (28), showing that DE change the expression for the approximated Euler equation by introducing a current inflation surprise term.

We provide an explicit solution for the model in Appendix C.²⁰

4.2 Diagnostic Expectations and the Possibility of Extra Amplification

A classic challenge in macroeconomic modeling is finding ways to generate realistic business cycles with shocks of moderate size. The literature has relied on multiple types of frictions (e.g. nominal, as in Christiano, Eichenbaum, and Evans 2005, or financial, as in Bernanke and Gertler 1989; Kiyotaki and Moore 1997), interactions in the form of strong complementarities (Benhabib and Farmer 1994), or multiple shocks

²⁰We assume that the determinacy and boundedness conditions are satisfied.

(Smets and Wouters 2007) to fit the data.

We demonstrate that diagnosticity provides a viable behavioral alternative to understand the large size of observed fluctuations within the NK model. Because diagnosticity leads agents to extrapolate the impact of exogenous shocks, expectations are more volatile. Intuitively, one would expect the DE-NK model to predict a higher volatility of output than under RE. Indeed, the following proposition establishes that diagnosticity can generate extra endogenous volatility in the NK model. We analytically prove this result when prices are completely rigid ($\psi_p \rightarrow \infty$).²¹

Proposition 2 (Extra Volatility: NK Model) *Consider the model given by (33)-(37). When $\psi_p \rightarrow \infty$ (rigid prices), output is more volatile under DE than under RE : $Var(\hat{y}_t^{DE}) > Var(\hat{y}_t^{RE})$. When $\psi_p \rightarrow 0$ (flexible prices), output volatility under DE is equal to that under RE.*

In the flexible price limit, we obtain the efficient benchmark where output volatility is equal to the stationary TFP process volatility. In the perfectly rigid price case, diagnosticity interacts with price rigidity to amplify fluctuations in output whenever $\theta > 0$. In the intermediate range, we numerically illustrate how excess volatility under DE varies with the degree of price rigidity, parameterized by $\kappa \equiv (1 + \nu)\tilde{\kappa}$. Our default calibration of the NK model is based on the textbook by Galí (2015).²² θ is set to 1 following Bordalo, Gennaioli, Shleifer, and Terry (2021). We obtain a standard deviation of output of 2.96%, relative to 1.82% under RE. Thus, output volatility increases by 63% due to DE.

DE interact with the nominal frictions embedded in the NK model in order to generate extra output volatility. Figure 3 plots the excess volatility under DE relative to RE as a function of κ plotted on the x-axis, for different values of θ . κ is inversely related to ψ_p , the adjustment cost parameter. Given the default calibration, DE generates highest excess volatility relative to RE when prices are perfectly rigid. Excess volatility monotonically declines as prices become flexible.²³ In the flexible price limit, the excess volatility converges to zero. Also, the excess volatility is increasing in the diagnosticity parameter.

In order to further demonstrate the interaction of nominal rigidities with diagnos-

²¹Away from this limit, we can use the solution of the model presented in the appendix and obtain a condition for extra volatility, but this condition is messy and does not lend itself to any clear interpretation.

²²We set $\beta = 0.99$, $\epsilon_p = 9$, $\phi_\pi = 1.50$, and $\phi_x = 0.5$. We set $\nu = 2$, and ψ_p such that $\kappa = 0.050$. The TFP process is calibrated with persistence 0.90 and standard deviation of 2%.

²³It is possible to get lower volatility of output under DE relative to RE for different parameter configurations. For example, when persistence of the TFP process $\rho_a = 0.1$, $\kappa = 1$, and $\theta = 1$, we obtain dampening of output volatility under DE relative to under RE.

Figure 3: Excess Volatility under DE, Baseline NK Model

Notes: The figure presents percentage points of volatility under DE relative to RE as a function of the slope of Phillips curve, κ , and for various values of diagnosticity parameter, θ . The model is given by equations (33)-(37). See Footnote 22 for the default calibration.

ticity, we consider the case of a frictionless real business cycle (RBC) model. The model is standard and is provided in Appendix D. There, we analytically show that output is less volatile under DE than under RE when there is full depreciation of capital ($\delta = 1$) and TFP shock process has zero persistence ($\rho_a = 0$). For a calibration away from these analytical assumptions, we find that the standard deviation of output is lower under DE than under RE.

To shed light on these results, it is useful to draw a parallel to the news shocks literature originating in the seminal work by Beaudry and Portier (2004) and Beaudry and Portier (2006). The addition of DE to the NK model can be seen as a way of generating *errors in expectations* that resemble news about the future. For instance, in the case of a positive TFP shock, agents extrapolate this shock, expecting a further positive TFP shock in the next period. Therefore, the TFP shock generates a contemporaneous raise in TFP, and an excessive increase in expectations about TFP in the next period. Shocks to expectations can be seen as shifts in aggregate demand. Whether aggregate demand can move away from aggregate supply depends on the degree of nominal rigidities. When prices are sticky, output is demand determined: The positive income effect raises consumption and in general equilibrium this effect dominates. Output ultimately increases. This explains the extra volatility afforded by the DE-NK model.²⁴ Similarly, in the presence of capital, shocks to expectations also face difficulties in generating comovement in a baseline, frictionless, RBC model with flexible prices (Beaudry and Portier 2006; Jaimovich and Rebelo 2009). Indeed, in the

²⁴To be clear, we use this parallel to news shocks only for the purposes of providing intuition. In fact, compared to news shocks, DE generate novel and different effects. Section 5 expands more on this point.

case of a positive news shock, the implied income effect produces a fall of labor supply and hence output (Barro and King 1984). However, as shown in Blanchard, L’Huillier, and Lorenzoni (2013), nominal rigidities are also a solution to this counterfactual prediction of the RBC model. Indeed, we return to this property of DE in the case of an estimated medium-scale DSGE models.²⁵

4.3 Keynesian Supply Shocks

Motivated by economic crisis caused by the COVID-19 pandemic, a rapidly growing literature focuses on constructing models that have the ability to generate a demand shortfall that is fundamentally caused by a disruption on the supply side of the economy, that is, a ‘Keynesian’ supply shock. Thus far, some of the candidate explanations for this phenomenon include multiple consumption goods (Guerrieri, Lorenzoni, Straub, and Werning 2022), endogenous firm-entry (Bilbiie and Melitz 2022), heterogeneous risk-tolerance (Caballero and Simsek 2021), and endogenous TFP growth (Fornaro and Wolf 2022). As the following proposition shows, DE present a behavioral mechanism capable of producing Keynesian supply shocks.

Proposition 3 (Keynesian Supply Shocks) *Consider the model given by (33)-(37). Assume that $\psi_p \rightarrow \infty$ and that the diagnosticity parameter is high enough, that is, $\theta > 2(1 - \rho_a)(1 + \phi_x)/(\phi_x \rho_a)$. Then, the output gap \hat{x}_t positively co-moves with the unanticipated component of TFP: $\frac{\partial \hat{x}_t}{\partial \varepsilon_{a,t}} > 0$.*

Similar to Proposition 2, the proposition imposes completely rigid prices for tractability. The result extends to the case of moderately rigid prices, as Figure 4 shows. We use same default calibration presented above. The figure plots the evolution of the output gap. Following a negative TFP shock, the economy enters a recession: the output gap falls under DE. In the RE case, the output gap moves in the opposite direction.

The key to this striking result is extrapolation: following the shock, agents extrapolate and become excessively pessimistic about future output. This leads to a large drop in consumption, which due to nominal rigidities, leads to contemporaneous fall in output. Due to diagnosticity, expectations become sufficiently pessimistic to induce a fall in output larger than the initial drop in TFP, generating a Keynesian recession.

²⁵The recent important paper by Bordalo, Gennaioli, Shleifer, and Terry (2021) presents another case in which DE interact with frictions to generate extra volatility. The paper looks at an RBC model with financial frictions on the firm side. Firms are heterogeneous. The paper shows that the interaction of firms’ expectations with financial frictions successfully generate amplification of investment and output dynamics, and fits a number of facts relating to credit cycles.

Figure 4: Output Gap Response to a Negative TFP Shock, Baseline NK Model

Notes: The figure depicts the impulse response of the output gap to a unit negative shock to TFP. The productivity shock process is given by equation (37). The solid line denote impulses responses with diagnostic expectations, whereas the dotted line denote responses with rational expectations. The dynamics of employment are exactly the same as the output gap.

This is in contrast to the result under RE where the fall in TFP, being only transitory, does not lead to a fall in aggregate demand. Hence, there is a boom: lower TFP for the same level of aggregate demand increases the demand for labor; this generates a boom in the labor market, together with a *rise* in the output gap.

A noteworthy result, following BGS, is that there is a systematic *reversal* of the output gap. The extrapolation of the current shock turns out to be incorrect under DE. Following a negative shock, agents become pessimistic and the output gap becomes negative. Next period, the excess pessimism subsides and the output gap is corrected upwards. Output gap forecast errors are predictable: diagnostic forecasts neglect the systematic reversal of the output gap.

4.4 Fiscal Policy Multiplier

Here we address the implications of DE for the size of the fiscal policy multiplier. There are two reasons to do this.

First, given the recent unprecedented fiscal response to the COVID-19 crisis in the U.S. and other countries, understanding the effects of fiscal policy is central. Also, substantial empirical evidence indicates that marginal propensities to consume are large (see Fagereng, Holm, and Natvik 2021, among others), or similarly, that fiscal multipliers are large in the cross section (Nakamura and Steinsson 2014).²⁶ We show that DE constitute a useful addition to the NK framework, because it generates novel, rich implications for the fiscal multiplier.

Second, this exercise is a natural path for understanding the endogenous extrap-

²⁶See Steinsson (2021) for a similar discussion.

olation generated by the diagnostic Fisher equation embedded in equation (25), as explained in Example 2, Section 3.

We add government spending shocks to the NK model. There is a balanced budget government spending financed by lump-sum taxes. Now, the total output in the economy is used for consumption and government expenditure. That is, we replace equation (36) with:

$$\hat{y}_t = \hat{c}_t + \hat{g}_t \quad (38)$$

where \hat{g}_t is the percentage change of government spending from its steady state as fraction of steady state output. \hat{g}_t follows an exogenous process:

$$\hat{g}_t = \rho_g \hat{g}_{t-1} + \varepsilon_{g,t} \quad (39)$$

where $\varepsilon_{g,t} \sim iid N(0, \sigma_g^2)$. The equilibrium is given by equations (33), (34), (35), and (38), for a given process (39).

For convenience, we write the diagnostic Fisher equation here:

$$\hat{r}_t = \hat{i}_t - \mathbb{E}_t[\hat{\pi}_{t+1}] - \theta(\mathbb{E}_t[\hat{\pi}_{t+1}] - \mathbb{E}_{t-1}[\hat{\pi}_{t+1}]) - \theta(\hat{\pi}_t - \mathbb{E}_{t-1}[\hat{\pi}_t]) \quad (40)$$

Extrapolation implied by DE reduces the real interest rate, and hence leads to higher multipliers. To isolate the implications of endogenous extrapolation, we look at i.i.d. government spending shocks. We obtain the following proposition.

Proposition 4 (Fiscal Policy Multiplier) *Consider the model given by equations (33), (34), (35), (38), and (39). Assume that $\phi_x = 0$ and that the persistence of the shock $\rho_g = 0$. Then:*

1. *Under rational expectations, the fiscal policy multiplier is always strictly less than 1. Under diagnostic expectations, the fiscal policy multiplier is greater than 1 if $\theta > \phi_\pi$, and less than 1 if $\theta < \phi_\pi$.*
2. *The fiscal policy multiplier is greater under diagnostic expectations than under rational expectations.*
3. *The fiscal policy multiplier is increasing in θ , and tends to infinity as $\theta \rightarrow \phi_\pi + \kappa^{-1}$.*

Hence, when the degree of diagnosticity is above the reaction parameter of the monetary authority, the multiplier is greater than one. The intuition for this result is as follows. The diagnostic real rate moves, in response to current inflation, due to the endogenous extrapolation (governed by θ), and by the response of the central bank. In

the RE benchmark, the multiplier is always smaller than 1 because the central bank moves the nominal rate to dampen the effect of fiscal policy. The condition $\theta > \phi_\pi$ ensures that endogenous extrapolation offsets this dampening.

The degree of diagnosticity parametrizes the multiplier, increasing it above the RE multiplier, and spanning the full range of values to infinity. We assume that $\phi_x = 0$ in order to get a clean and easy to interpret condition such that the multiplier is greater than 1 in the DE model.²⁷

This analytical case highlights that the higher multiplier under DE is only working through the term $\theta(\hat{\pi}_t - E_{t-1}[\hat{\pi}_t])$ in the diagnostic Fisher equation. Given that the shock is i.i.d., $\theta(E_t[\hat{\pi}_{t+1}] - E_{t-1}[\hat{\pi}_{t+1}])$ is zero. Extrapolation is purely endogenous, working through the extrapolation of current innovations to inflation, thereby generating the expansionary effect discussed in Example 2 above.

We move away from the default calibration to illustrate the results in the case $\phi_x = 0$. In order to illustrate a case where the multiplier is greater than 1, we consider a dovish interest rate rule ($\phi_\pi = 1.1$) and a moderately higher diagnosticity parameter of $\theta = 1.5$. Using a persistence of the government shock equal to 0.5 generates a DE multiplier of 1.04, and an RE multiplier of 0.91. Raising the diagnosticity parameter slightly generates much larger multipliers. Furthermore, using a steeper Phillips curve (say, $\kappa = 0.20$) strengthens the endogenous inflation extrapolation channel: the DE multiplier is now 1.13, for an RE multiplier of 0.73.

We conclude this section by noting that DE do not always lead to higher multipliers. When government shocks are persistent, exogenous extrapolation kicks in. The expectation of future spending crowds out current consumption, reducing output. With DE, expectations of future spending are exaggerated, and can considerably reduce multipliers when persistence is high. To illustrate this, we go back to our default calibration. In addition, we set the persistence of the shock to 0.9. In this case, the RE multiplier is 0.17, for a DE multiplier of -0.32. In this simulation, the exogenous extrapolation channel is so strong that it dominates the endogenous extrapolation channel, leading to a negative multiplier.

5 Empirical Evaluation

Given the theoretical findings of the previous sections, we undertake an empirical evaluation of diagnostic expectations using standard structural methods. The primary goal is to ask the following question. Consider a baseline, medium scale, rational ex-

²⁷The general condition is $\theta \geq \phi_\pi + \frac{\phi_x}{(1-\psi)\kappa}$.

pectations DSGE model. Replace rational expectations with diagnostic expectations. (The diagnostic model nests the rational expectations model via the diagnosticity parameter.) Is there evidence that diagnostic expectations improve the ability of the DSGE model to fit business cycle data?

With this formulation of the broad question that guides our empirical investigation, four interrelated subquestions emerge: What is the estimated value of the diagnosticity parameter? Does the credible interval span the RE limit? Ultimately, is there statistical evidence that diagnosticity provides an advantage when fitting business cycle data? If so, what changes in the interpretation of the data?

Given the recent interest in the literature on survey data (see Bordalo, Gennaioli, Ma, and Shleifer 2020, Coibion and Gorodnichenko 2015b, among others), we include five survey forecast series from the Survey of Professional Forecasters (SPF) among the set of observable variables. The goal is to use these data to discipline belief formation in the estimated model. Recently, Milani and Rajbhandari (2020) and Miyamoto and Nguyen (2020) have shown that DSGE models featuring news shocks can fit SPF data.²⁸ Hence, we also include news and noise shocks in the estimation, based on the specification by Blanchard, L’Huillier, and Lorenzoni (2013) (henceforth BLL). In model evaluation, Chahrour and Jurado (2018) find BLL to be the best candidate for fitting the data with shocks to rational expectations, such as news or noise.²⁹

Thus, we highlight that our empirical exercise is disciplined by the addition of a host of ingredients in the baseline model: a rich set of frictions, shocks and competing channels. This includes the frictions introduced in the seminal work by Christiano, Eichenbaum, and Evans (2005). We include the exogenous driving processes introduced by Smets and Wouters (2007). We include news shocks as an alternative channel to explain expectations. We include information frictions in the form of noise shocks (included in the news and noise specification by BLL). By adding all these bells and whistles (nominal, real, and information frictions), driving processes, and the alternative expectation channel, we aim to perform a tough test of the usefulness of the behavioral friction embodied by diagnostic expectations. Indeed, we want to assess whether it provides a significant empirical advantage, *even when* all the other commonly used ingredients have been included.

²⁸Related work by the Federal Reserve Bank of New York has included data on inflation and Federal Funds Rate expectations in DSGE estimation (Del Negro et al. 2013).

²⁹“News and noise” models of belief-driven fluctuations are models where rational agents receive noisy advance information about fundamental shocks hitting the economy.

5.1 Medium-Scale DSGE Model

Since the model is standard (Christiano, Eichenbaum, and Evans 2005), we describe here its main ingredients and relegate the details to the appendix. The preferences of the representative household feature habit formation and differentiated labor supply. The capital stock is owned and rented by the representative household, and the capital accumulation features a quadratic adjustment cost in investment, as introduced by Christiano et al. (2005). The model features variable capacity utilization.

The final good is a Dixit-Stiglitz aggregate of a continuum of intermediate goods, produced by monopolistic competitive firms, with Rotemberg (1982) costs of price adjustment. Similarly, specialized labor services are supplied under monopolistic competition, with Rotemberg (1982) costs of nominal wage adjustment. The monetary authority sets the nominal interest rate following an inertial Taylor rule.

The model features eight persistent structural shocks: shocks to temporary and permanent productivity, a noise shock to the signal about permanent productivity, a shock to the marginal efficiency of investment, shocks to price and wage markups, shocks to monetary and fiscal policy. We introduce i.i.d. measurement errors for SPF forecasts.³⁰

Following Smets and Wouters (2007) and Justiniano, Primiceri, and Tambalotti (2010), the model is estimated based on U.S. time series for GDP growth, consumption growth, investment growth, employment, the federal funds rate, inflation, and wages, for the period 1954:III-2004:IV. This sample period facilitates comparison of our results across models in the robustness section, and avoids complications arising from the zero lower bound. We also include SPF data on consumption growth, investment growth, output growth, short-term inflation and short-term interest rate forecasts. The data appendix presents more details. We set up a Kalman filter to get smoothed estimates of the permanent component of productivity and the associated agents' beliefs. Table 7 in the appendix presents the parameter prior distributions. We generate 5,000,000 draws using a Metropolis-Hastings algorithm and discard the first 20% as initial burn-in.

5.2 Results

The parameter estimates are reported in Table 1. We report mean posterior estimates, along with the 90% credible interval. We present estimates for the diagnostic model and the rational model, side-by-side. The bottom row reports the marginal likelihood

³⁰The two productivity shocks are not separately observed by the agent. Instead, a public signal on permanent productivity is available. These three variables imply a distributed lag model for TFP and beliefs about long-run income.

for both models.

Notes: Priors are given in Table 7 in the appendix.

Let us first look at the estimate of the diagnosticity parameter θ . Our prior distribution is normal with mean 1 and standard deviation 0.3. The estimated posterior mean for θ is 0.7325. This estimate is close to the one obtained in the previous empirical exercises reported by Bordalo, Gennaioli, Ma, and Shleifer (2020), and to the value used by Bordalo, Gennaioli, Shleifer, and Terry (2021). Figure 8 in the appendix shows that the posterior distribution of θ is unimodal. The 90% credible interval covers values from 0.5917 to 0.8746, away from the RE limit of zero.

In order to understand the implications of DE, we analyze the impulse response functions (IRFs) to the main driving processes.³¹ Figure 5 plots IRFs for the one-step-ahead consumption forecast, and for selected quantities (consumption and output growth, specifically). Figure 6 plots these IRFs for selected prices (price inflation, nominal and real interest rates).

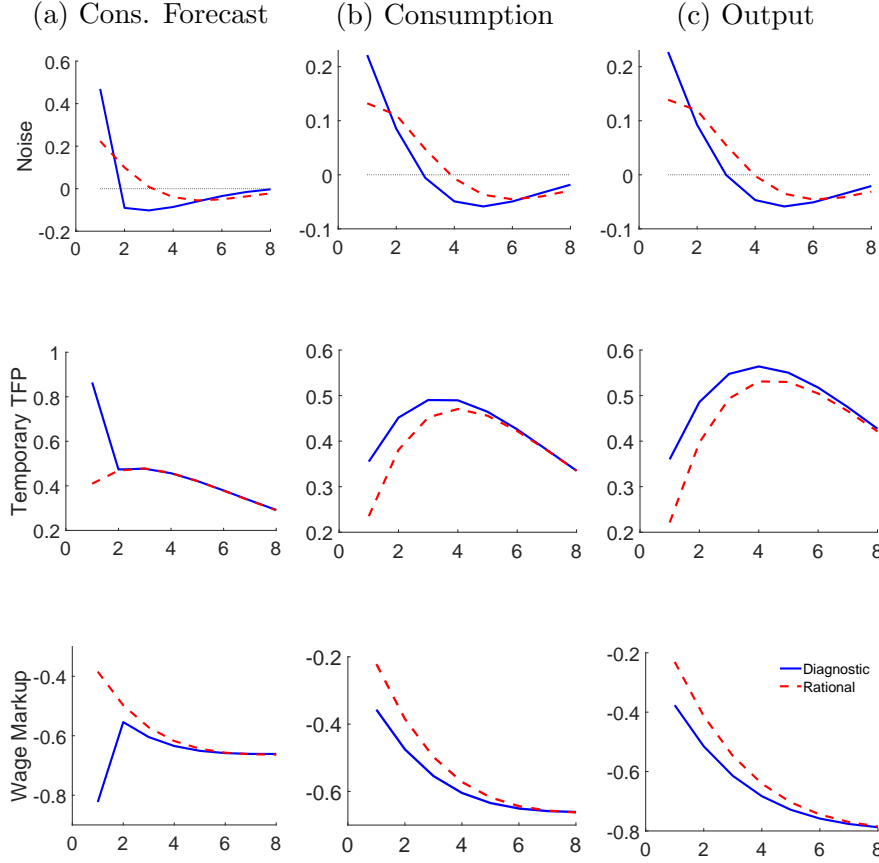

Consider the IRFs to the noise shock. In this model, the noise shock raises expectations of future income. Lorenzoni (2009) shows that this causes the consumer to increase spending, raising aggregate demand. Firms increase investment in anticipation of higher profits. As a consequence of this mechanism, the noise shock increases consumption and output in the DE model (solid line). The same happens in the RE counterfactual, obtained by shutting down diagnosticity ($\theta = 0$, dashed line). Focusing on the consumption forecast, we see that the behavioral consumer's beliefs overreact to the shock, exhibiting a more volatile response, and a rapid reversal relative to RE. The combination of excess volatility and reversal results in a boom-bust in actual consumption and economic activity more broadly, above and beyond the mechanical reversal generated with the Kalman filter in the RE counterfactual. Consumption habits introduce persistence in consumption and dampen the actual response of consumption relative to that of the forecast. The boom-bust in the consumption forecast is, hence, more pronounced than the boom-bust in consumption.

Turning to the IRFs of prices, we note that price inflation overreacts on impact of the shocks. This is due to the forward-looking behavior of prices: By the logic of the NK Phillips curve, current inflation depends on the expectation of future inflation. For instance, following a positive TFP shock, inflation falls by a larger amount under DE than under RE.

Another noticeable difference between the DE model and the RE counterfactual emerges from the responses of the real rate (top-right plot, Figure 6). As discussed in Section 3.2.2, the expression for the diagnostic real rate features an extra term $\theta(\hat{\pi}_t - E_{t-1}[\hat{\pi}_t])$, whereby current surprise inflation is extrapolated into future prices.

³¹We plot the IRFs of the shocks that explain the highest share of consumption volatility on impact.

Figure 5: Impulse Responses: Quantities

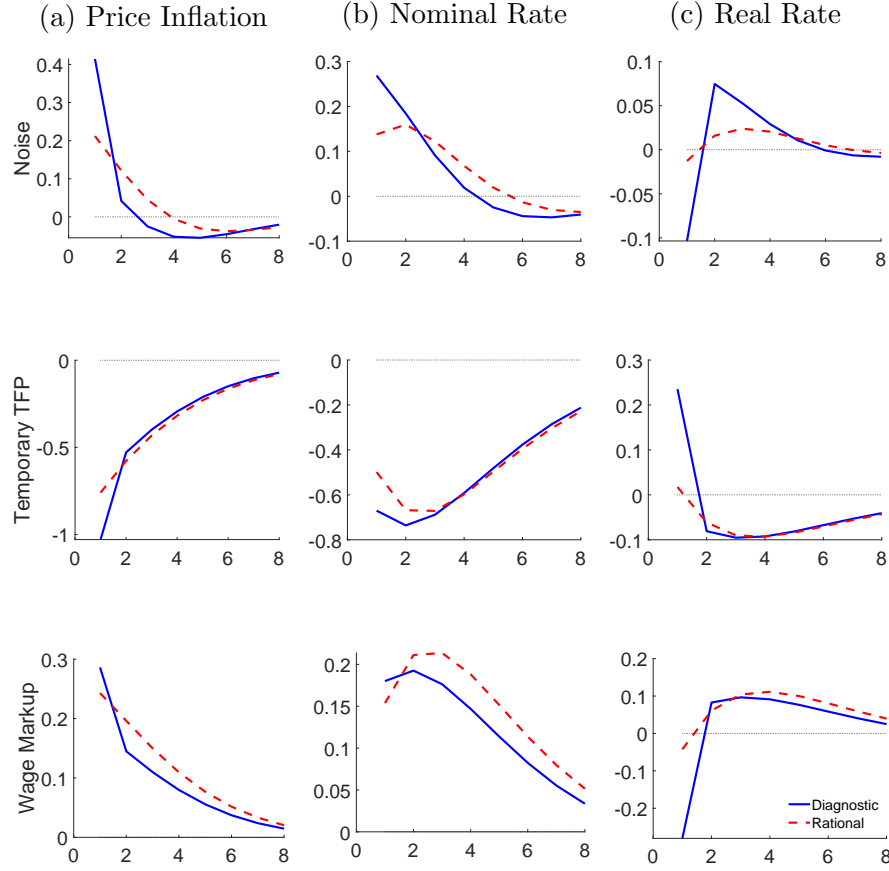

Notes: The panels depict the impulse responses of one-step-ahead consumption forecast, consumption, and output to a one standard deviation shock to noise signal, temporary TFP, and wage markup. The solid lines denote impulses responses with diagnostic expectations, whereas the dashed lines denote responses with rational expectations. We plot the estimated DE model and the RE counterfactual ($\theta = 0$). See Table 1 for parameters.

As a result, the real rate exhibits marked boom-bust dynamics. For instance, looking at the response to a noise shock, we see that the diagnostic real rate drops on impact since inflation has unexpectedly increased, and then turns positive in the next period. Similar to our previous applications, these reversal dynamics are systematically neglected by diagnostic agents.

Overall, comparing the IRFs of the DE model and the RE counterfactual suggests that the DE model affords extra volatility of endogenous variables in general equilibrium. This theme was developed analytically at the beginning of Section 4, and linked to nominal rigidities. To quantify this point we compute the excess unconditional volatility afforded by DE for consumption growth, output growth, price and wage inflation, and the real rate. Among these, the largest increase is the one of the real rate, with a 37% increase in volatility. The increase of consumption volatility is particularly

Figure 6: Impulse Responses: Prices

Notes: The panels depict the impulse responses of inflation, the nominal interest rate, and the real rate to a one standard deviation shock to noise signal, temporary TFP, and wage markup. The solid lines denote impulses responses with diagnostic expectations, whereas the dashed lines denote responses with rational expectations. We plot the estimated DE model and the RE counterfactual ($\theta = 0$). See Table 1 for parameters.

strong as well, at 23%. This amplification is consistent with overreaction in consumers' expectations about future consumption, and with the boom-bust dynamics of the diagnostic real rate. The volatility of other variables increase as well (see Table 8 in the appendix).

We use the Bayes factor to empirically evaluate the fit of the diagnostic model against the rational model. The log marginal likelihood of the data given the estimated diagnostic model is -1812.71. This statistic is lower, -1847.38, in the case of the rational counterpart. This difference in log marginal likelihoods represents evidence in favor of the diagnostic model.³²

³²Following the Kass and Raftery (1995) classification, $2\log(BF) = 2 \times 34.67 = 69.34$ statistic represents "very strong evidence" in favor of the diagnostic model. This statistic has been used for model comparisons in the DSGE literature. See, for example, Ascari, Bonomolo, and Lopes (2019).

We look at the forecast error variance decompositions to get intuition into how the DE model fits the data and outperforms the RE model. In order to assess which shocks account for short-run volatility, Table 2 presents the one-step-ahead variance decomposition across all structural shocks for quantities and prices. For each, we first present the case of the DE model. Then, for comparison, we present the variance decomposition for the estimated RE model (with parameter estimates presented in Table 1). A striking finding is that the DE model relies much less on noise shocks to explain consumption fluctuations. The contribution of noise shocks to consumption volatility is only 12% in the DE model (compared to 43% in the RE model), and to output is 7% in the DE model (compared to 25% in the RE model). Other shocks explain these variables, with temporary TFP shocks explaining 30% of consumption and 18% of output volatility in the DE model (versus 15% and 7% in the RE model), and with wage markup shocks explaining 30% of consumption and 19% output volatility (versus 1% and 1% in the RE model).³³

What explains this pattern? The DE model exploits the rich propagation afforded by extrapolation in the forward-looking behavior of consumers, firms, workers, and financial markets. Consumers extrapolate, generating extra volatility and reversals of consumption. Firms extrapolate, generating extra volatility and reversals of investment. Price and wage setters extrapolate, generating extra volatility and reversals in price and wage inflation. Financial markets extrapolate, generating extrapolation of current surprise inflation when pricing nominal bonds, together with implied dynamics of the real rate. Instead, in the case of the RE model, errors in expectations arise only about future income, following the permanent income channel emphasized by BLL, who build on Lorenzoni (2009). Overall, the DE model affords a more flexible structure of errors in expectations, and is able to explain deviations from belief rationality on several dimensions. This finding can be interpreted as evidence that DE outcompete noise shocks as a preferred channel to explain fluctuations. Consistent with this view, we point to the fact that the estimated noise in the signal, σ_s , is 0.5400 in the DE model (versus 1.0594 in the RE model). The DE model fits the data with a more precise signal and therefore a lower degree of information imperfections. It explains fluctuations with the aid of other shocks, which employ diagnosticity in order to propagate internally in general equilibrium.

We also note the sharp drop in the importance of exogenous markups in explaining price and wage inflation variance. Indeed, price markup shocks explain 33% of price inflation volatility in the DE model (versus 59% in the RE model). Similarly, wage

³³Chahrour and Jurado (2018) propose a variance decomposition of news and noise in terms of fundamental shocks and noise. For ease of comparison, we retain the original BLL decomposition.

Table 2: Variance Decomposition: Quantities and Prices

Notes: The one-step-ahead variance decomposition is performed at the mean of each specification. The decomposition for the RE model is obtained using the estimated parameters reported in Table 1 (RE estimated).

markup shocks explain 22% of wage inflation volatility in the DE model (versus 67% in the RE model). The DE model exploits the forward-looking behavior of wage setters to explain goods prices and wages, relying more on other shocks and internal propagation mechanisms. For instance, temporary TFP shocks explain 41% of price inflation volatility in the DE model (versus 29% in the RE model). Also, *price* markup shocks explain 41% of *wage* inflation volatility in the DE model, instead of 24% of wage inflation volatility in the RE model. Consistent with this finding on the variance decomposition, the wage Phillips curve is steeper in the DE model, as evidenced by a

much lower Rotemberg costs parameter.

Table 3 presents one-step-ahead variance decomposition for the forecast data, distinguishing between the relative contribution of structural shocks to that of observation errors in terms of short-run volatility. We find that the structural shocks account for a higher share of the short-run empirical volatility of forecast data in the DE model. For instance, 44% of the one-step-ahead consumption forecast is explained by structural shocks in the DE model (versus 31% in the RE model), and 56% of the one-step-ahead inflation forecast volatility is explained by structural shocks in the DE model (versus 33% in the RE model).

Table 3: Variance Decomposition: One-Step-Ahead Forecasts

Variable	Structural Shocks	Measurement Errors
<i>Consumption</i>		
DE	0.44	0.56
RE	0.30	0.70
<i>Investment</i>		
DE	0.33	0.67
RE	0.17	0.83
<i>Output</i>		
DE	0.44	0.56
RE	0.31	0.69
<i>Price Inflation</i>		
DE	0.56	0.44
RE	0.33	0.67
<i>Nominal Rate</i>		
DE	0.91	0.09
RE	0.76	0.24

Notes: The one-step-ahead variance decomposition is performed at the mean of each specification. The decomposition for the RE model is obtained with the estimated parameters reported in Table 1 (DE) and setting $\theta = 0$ (RE counterfactual).

This analysis points to two primary reasons that explain the empirical success of the DE model.

First, diagnosticity is a powerful and flexible amplification mechanism, generating errors in expectations along several dimensions. To shed light on the implications of this finding, we draw on a previously documented caveat of the news and noise model under RE when it comes to fitting business cycle data. Despite embodying the best

candidate model to explain business cycle fluctuations based on shocks to rational expectations (Chahrour and Jurado 2018), the news and noise model is known to deliver a poor fit of the interest rate rule. Indeed, as discussed in BLL (pp. 3064-5), an empirically successful propagation of noise shocks requires either an unrealistically dovish monetary authority, or unrealistically flat Phillips curves. This is a consequence of the standard specification of log utility in consumption, which sets the intertemporal elasticity of substitution to one, making consumption highly sensitive to the real interest rate. Hence, a hawkish interest rate rule can easily mitigate the propagation of noise shocks in the RE model. Consistent with the previous literature, our RE estimates feature an unrealistically dovish interest rule, with a point estimate of ϕ_π at 1.07, close to the estimate in BLL at 1.01. This value is much smaller than the one obtained, for instance, by Smets and Wouters (2007) ($\phi_\pi = 2.04$), or by Justiniano, Primiceri, and Tambalotti (2010) ($\phi_\pi = 2.09$).

This fact provides a valuable insight into the superior empirical performance of the DE model. As discussed in the context of the variance decomposition Table 2, DE generate errors in expectations along several dimensions. The RE model, instead, generates errors in expectations only through the effects of exogenous shifts in expectations of future income through noise shocks (Lorenzoni 2009). Hence, a lower reliance on noise shocks in the DE model allows to improve the fit of the monetary policy rule. By way of implication, the coefficient ϕ_π is estimated at 1.54, more in line with the rest of the literature.³⁴ Endogenous errors in expectations using DE constitute a step forward in the specification of DSGE models for business cycle analysis.

As a case in point, the implications of alternative interest rate rule estimates can be seen by considering the path of interest rate forecasts in the last recession in our sample. In the first quarter of 2001, the U.S. economy entered the dot-com bubble recession. An ensuing Federal Reserve's easing cycle brought the effective Federal Funds Rate down from 6.52% to 1.00%. One-quarter-ahead interest rate forecasts also adjusted downwards. Figure 7 presents the actual and the model-implied forecasts, both under DE and under RE (with respective parameter estimates presented in Table 1).³⁵ Actual forecasts are plotted with the solid line and circle markers; DE forecasts are plotted with solid line and no markers; RE forecasts are plotted with the dashed line. Consistent with the improved estimate of the systematic component of monetary policy and the extrapolative nature of beliefs, the DE model forecasts track the actual

³⁴Note, both Phillips curves are also slightly steeper in the DE model. Such parameter estimates significantly dampen the equilibrium effects of noise shocks and its relative importance as an explanatory mechanism, as shown in Table 2.

³⁵With the help of measurement errors, both models obviously generate a path of forecasts that exactly matches the data. We look at the model-implied forecasts *conditional on structural shocks only*.

Figure 7: Interest Rate Forecasts: SPF and Model-Implied

Notes: The figure depicts the path of interest rate (one-period ahead, annualized) forecasts (solid line, circle markers), together with their model-implied counterpart under DE (solid line) and RE (dashed line) from 2000:Q2 to 2004:Q3. The path for the RE model is obtained using the estimated parameters reported in Table 1 (RE estimated).

forecasts more closely over this period. The RE model, with a less reactive monetary policy rule (lower ϕ_π and ϕ_x), under-predicts the extent of the decline in actual forecasts.³⁶

The second fact that embodies the empirical success of DE is the following. The DE model is able to explain price and wage dynamics inflation *internally*, relying less on exogenous markup drivers, as evidenced by the variance decomposition Table 2. Consistent with this view, we highlight that the standard deviation of price markup shock σ_μ is estimated at 0.1591 in the DE model (versus 0.1998 in the RE model).³⁷ We interpret the fact that price and wage fluctuations are explained internally, rather than exogenously, as an encouraging finding. This is because DSGE models could be criticized on the grounds that markup shocks constitute a rather black-boxy ingredient without a realistic counterpart (Chari, Kehoe, and McGrattan 2009).

5.3 Robustness

5.3.1 Prior on the Diagnosticity Parameter θ Centered at Zero

The model can in principle fit the data with a value of θ that is either close to zero, or negative. Thus, it is important to check that imposing a prior distribution centered at

³⁶More broadly, and consistent with our reported estimates of the standard deviation of measurement errors, the RMSE of model-implied forecasts based on structural shocks reveals that the DE model tracks the actual forecast data more closely than the RE model for 3 out of 5 forecast series (output growth, investment growth, and consumption growth). For the interest rate forecast, this is also the case in the second part of the sample (1990:I onwards).

³⁷The estimated standard deviation of wage markup shocks is also lower, 0.44 in the DE model, versus 0.45 in the RE model.

a positive value (such as 1) does not importantly affect our results. Using a symmetric prior distribution around 0 ($\theta \sim N(0.0.3)$), we re-estimate the DSGE model under DE. Table 9 in the appendix presents the results. Our posterior estimate of θ is not importantly affected, with a mean posterior of 0.6537. Again, the 90% credible interval is away from zero, covering values from 0.5193 to 0.7884, away from the RE limit of zero. The log marginal likelihood is also higher for the DE model than for the RE model (-1814.82 versus -1847.38).

5.3.2 Diagnostic Expectations in Alternative Off-The-Shelf Models

Another robustness check concerns the importance of details of our implementation for the conclusion that DE provide a superior fit of business cycle data. There are two separate angles of potential concern. First, does this conclusion crucially depend on using the BLL model? Second, does this conclusion crucially depend on including SPF data among the set of observable variables?

In order to demonstrate that the answer to both these questions is negative, here, we undertake the estimation of two influential off-the-shelf DSGE models: Smets and Wouters (2007) and Justiniano, Primiceri, and Tambalotti (2010). In the estimation of each of this models, we make sure to replicate the authors' procedure as close as possible: We use the same sample 1954:III–2004:IV. We use their data set, ensuring variable construction does not cause any differences. We also set the same prior distribution. Hence, our RE results replicate their findings. The introduction of DE in this case constitutes a particularly tight test that DE are useful to explain business cycle data.

Table 11 in the appendix presents the results for the Smets and Wouters (2007) model. We present estimates for this model under diagnosticity, and for the baseline the rational model, side-by-side.³⁸ Our posterior estimate of θ is smaller than under BLL, but still positive with a mean posterior of 0.4435. The 90% credible interval is away from the RE limit of zero, covering values from 0.1822 to 0.6928. The log marginal likelihood is also higher for the DE model than for the RE model (-897.91 versus -900.69).

Table 13 in the appendix presents the results for the Justiniano, Primiceri, and Tambalotti (2010) model. We present estimates for this model under diagnosticity, and for the baseline the rational model, side-by-side. Our posterior estimate of θ is smaller than under BLL but still positive with a mean posterior of 0.4336. The 90%

³⁸For the RE model, we obtain a similar slope of the price and wage Phillips curves despite the use of Rotemberg adjustment costs instead of Calvo in our specification of nominal rigidities.

credible interval is away from the RE limit of zero, covering values from 0.1894 to 0.6745.³⁹ The log marginal likelihood is also higher for the DE model than for the RE model (-1190.86 versus -1193.78).

6 Conclusion

In this paper, we argue that diagnostic expectations constitute a behavioral mechanism that can be fruitfully incorporated into New Keynesian macroeconomics. To this end, we first considered a set of challenges encountered by researchers working with this type of models, and revisited them analytically under diagnostic expectations. We concluded that the use of diagnostic expectations opens up avenues to make significant progress in the context of these challenges. We then asked if diagnostic expectations are validated empirically. Using a rich medium-scale DSGE model with news shocks and imperfect information, we conclude that the answer to this question is yes: The diagnostic model dominates the rational counterpart in terms of fit. This conclusion is robust to the consideration of other benchmark models.

Our general solution method offers opportunities to explore and revisit a number of themes in macroeconomics and international macroeconomics in the context of diagnostic expectations. For example, a challenge in open economy models has been to account for the cyclicalities of the current account in emerging countries, or to improve our understanding of exchange rate predictability. Furthermore, it would be fruitful to extend this solution method to nonlinear settings, such as monetary models where the zero lower bound constraint on nominal interest rates is imposed. Finally, our paper uses the property of the representativeness heuristic that innovations to predetermined variables produce a form of cue-dependence which distorts beliefs about future outcomes. A robust literature in psychology and behavioral economics provides foundations for a wide range of inconsistencies that depend on selective and associative memory (Kahana 2012; Bordalo, Conlon, Gennaioli, Kwon, and Shleifer 2023). Understanding the theoretical and empirical underpinnings of cues based on predetermined variables is an important avenue for research. We leave these explorations to future work.

³⁹In unreported results, we find that diagnosticity also generates extra volatility for output, consumption, investment, price inflation, wage inflation, and the real rate, for both the Smets and Wouters (2007) and the Justiniano et al. (2010) models.

A Proofs for RE Representation Result

This appendix collects all proofs for the results stated in Section 3. Standard matrix operations to obtain the solution, and associated proofs (needed once the RE representation has been obtained), are discussed in Appendix B.

A.1 Diagnostic Expectation Formula

Suppose that x_t follows an univariate AR(1) process, $x_t = \rho_x x_{t-1} + \varepsilon_t$, with $\varepsilon_t \sim i.i.d. N(0, \sigma_\varepsilon^2)$. Given (realized) states \check{x}_t and \check{x}_{t-1} , the diagnostic probability distribution function of x_{t+1} is

$$f_t^\theta(x_{t+1}) = f(x_{t+1}|x_t = \check{x}_t) \cdot \left[\frac{f(x_{t+1}|x_t = \check{x}_t)}{f(x_{t+1}|x_t = \rho_x \check{x}_{t-1})} \right]^\theta \cdot C \quad (41)$$

When looking at equation (41), it is important to notice that, generically, $\check{x}_t \neq \rho_x \check{x}_{t-1}$ (due to the realization of the shock ε_t .) However, since ε_t is fixed at 0 by the NNA, then

$$f(x_{t+1}|x_t = \rho_x \check{x}_{t-1}) \propto \varphi\left(\frac{x_{t+1} - \rho_x^2 \check{x}_{t-1}}{\sigma_\varepsilon}\right) \quad (42)$$

Thanks to the NNA, the variance of this pdf is σ_ε^2 , which is the same as the variance of the true pdf of x_{t+1} . Thus, the true and the reference distributions have the same variance. This ensures tractability.

We now prove that the diagnostic expectation of a univariate variable can be expressed in terms of rational expectations.

Lemma 1 (Univariate RE Representation) *Suppose that x_t follows an AR(1) process and that the NNA holds. Then,*

$$\mathbb{E}_t^\theta[x_{t+1}] = \mathbb{E}_t[x_{t+1}] + \theta(\mathbb{E}_t[x_{t+1}] - \mathbb{E}_{t-1}[x_{t+1}]) \quad (43)$$

Proof (Lemma 1.) The diagnostic expectation of x_{t+1} is given by

$$\mathbb{E}_t^\theta[x_{t+1}] = \int_{-\infty}^{\infty} x f_t^\theta(x) dx \quad (44)$$

The diagnostic pdf is given by

$$f_t^\theta(x) = \frac{\left[\frac{1}{\sigma_\varepsilon} \varphi \left(\frac{x - \rho_x \check{x}_t}{\sigma_\varepsilon} \right) \right]^{1+\theta}}{\left[\frac{1}{\sigma_\varepsilon} \varphi \left(\frac{x - \rho_x^2 \check{x}_{t-1}}{\sigma_\varepsilon} \right) \right]^\theta} C \quad (45)$$

where C is a normalizing constant given by

$$C = \exp \left\{ -\frac{1}{2} \left(\frac{\theta(1+\theta)\rho_x^2 \check{x}_t^2 + \theta(\theta+1)\rho_x^4 \check{x}_{t-1}^2 - 2(1+\theta)\theta\rho_x^3 \check{x}_t \check{x}_{t-1}}{\sigma_\varepsilon^2} \right) \right\} \quad (46)$$

in which case

$$\begin{aligned} \mathbb{E}_t^\theta[x_{t+1}] &= \int_{-\infty}^{\infty} x f_t^\theta(x) dx \\ &= \int_{-\infty}^{\infty} x \frac{1}{\sigma_\varepsilon} \varphi \left(\frac{x - (\rho_x \check{x}_t + \theta(\rho_x \check{x}_t - \rho_x^2 \check{x}_{t-1}))}{\sigma_\varepsilon} \right) dx \end{aligned} \quad (47)$$

Thus, the diagnostic distribution $f_t^\theta(x_{t+1})$ is normal with variance σ_ε^2 and mean

$$\mathbb{E}_t^\theta[x_{t+1}] = \mathbb{E}_t[x_{t+1}] + \theta(\mathbb{E}_t[x_{t+1}] - \mathbb{E}_{t-1}[x_{t+1}]) \quad (48)$$

■

In formula (43), the lagged expectation $\mathbb{E}_{t-1}[x_{t+1}]$ is the expectation conditional on information available at $t-1$, that is, conditional on \check{x}_{t-1} . Thus, $\mathbb{E}_t[x_{t+1}] = \rho_x \check{x}_t$ and $\mathbb{E}_{t-1}[x_{t+1}] = \rho_x^2 \check{x}_{t-1}$. For a given realized $\check{\varepsilon}_t$, this proof implies that:

$$\mathbb{E}_t^\theta[x_{t+1}] = \mathbb{E}_t[x_{t+1}] + \theta\rho_x \check{\varepsilon}_t > \mathbb{E}_t[x_{t+1}] \quad (49)$$

if and only if $\check{\varepsilon}_t > 0$, that is diagnostic expectations indeed extrapolate the past shock into future beliefs.

Extension to Multivariate Case. Assume that the vector \mathbf{z}_t follows a multivariate AR(1) process, $\mathbf{z}_t = \mathbf{A}_\mathbf{z} \mathbf{z}_{t-1} + \mathbf{w}_t$, where $\mathbf{w}_t \sim N(0, \Sigma_\mathbf{w})$, and $\mathbf{A}_\mathbf{z}$ is a persistence matrix. (Notice that we do not require orthogonality.)

We make the following multivariate no-news assumption (henceforth NNA) for any Gaussian AR(1) vector \mathbf{z}_{t+1} .

Assumption 2 (Multivariate No-News Assumption)

$$f(\mathbf{z}_{t+1} | - G_t) = f(\mathbf{z}_{t+1} | \mathbf{z}_t = \mathbf{A}_z \check{\mathbf{z}}_{t-1}) \quad (50)$$

The extension to the multivariate case is based on the fact that each element of the vector is univariate normal.

Lemma 2 (Multivariate DE Formula) *Assume that the vector \mathbf{z}_t follows a multivariate AR(1) process. Then,*

$$\mathbb{E}_t^\theta[\mathbf{z}_{t+1}] = \mathbb{E}_t[\mathbf{z}_{t+1}] + \theta(\mathbb{E}_t[\mathbf{z}_{t+1}] - \mathbb{E}_{t-1}[\mathbf{z}_{t+1}]) \quad (51)$$

Proof (Lemma 2). The proof proceeds element-by-element of the vector \mathbf{z}_{t+1} . Without loss of generality, consider the first element $\mathbf{z}_{1,t+1}$. The marginal distribution of $\mathbf{z}_{1,t+1}$ is also normal, and thus, under the NNA,

$$\mathbb{E}_t^\theta[\mathbf{z}_{i,t+1}] = \mathbb{E}_t[\mathbf{z}_{i,t+1}] + \theta(\mathbb{E}_t[\mathbf{z}_{i,t+1}] - \mathbb{E}_{t-1}[\mathbf{z}_{i,t+1}]) \quad (52)$$

The proof for the other elements of \mathbf{z}_t is identical. ■

Equation (17) follows from this lemma.

A.2 Existence and Uniqueness of the Rational Expectations Representation for the General Linear Model

The proof uses the fact that endogenous variables of the DSGE model are normally distributed, allowing to use the multivariate BGS formula (17), together with the linearity of the RE operator. First, we need to prove the following lemma.

Lemma 3 (Distribution of the Linear Combination $\mathbf{F}\mathbf{y}_{t+1} + \mathbf{G}_1\mathbf{y}_t + \mathbf{M}\mathbf{x}_{t+1} + \mathbf{N}_1\mathbf{x}_t$)
Consider the multivariate process (13) and model (18). The vector $\mathbf{F}\mathbf{y}_{t+1} + \mathbf{G}_1\mathbf{y}_t + \mathbf{M}\mathbf{x}_{t+1} + \mathbf{N}_1\mathbf{x}_t$ follows a multivariate normal distribution.

Proof (Lemma 3). First,

$$\mathbf{M}\mathbf{x}_{t+1} \sim N(\mathbf{M}\mathbf{A}\check{\mathbf{x}}_t, \mathbf{M}\Sigma_v\mathbf{M}') \quad (53)$$

Also,

$$\mathbf{F}\mathbf{y}_{t+1} \sim N(\mathbf{F}\mathbf{P}\check{\mathbf{y}}_t + \mathbf{F}\mathbf{Q}\mathbf{A}\check{\mathbf{x}}_t, \mathbf{F}(\mathbf{Q} + \mathbf{R})\Sigma_v(\mathbf{Q} + \mathbf{R})'\mathbf{F}') \quad (54)$$

Finally,

$$\begin{aligned} \mathbf{F}\mathbf{y}_{t+1} + \mathbf{G}_1\mathbf{y}_t + \mathbf{M}\mathbf{x}_{t+1} + \mathbf{N}_1\mathbf{x}_t &\sim N((\mathbf{F}\mathbf{P} + \mathbf{G}_1)\check{\mathbf{y}}_t + ((\mathbf{F}\mathbf{Q} + \mathbf{M})\mathbf{A} + \mathbf{N}_1)\check{\mathbf{x}}_t, \\ &(\mathbf{F}(\mathbf{Q} + \mathbf{R}) + \mathbf{M})\Sigma_v(\mathbf{F}(\mathbf{Q} + \mathbf{R}) + \mathbf{M})') \end{aligned} \quad (55)$$

■

Proof (Proposition 1). Lemma 3 shows $\mathbf{F}\mathbf{y}_{t+1} + \mathbf{G}_1\mathbf{y}_t + \mathbf{M}\mathbf{x}_{t+1} + \mathbf{N}_1\mathbf{x}_t$ is multivariate Gaussian. As a consequence of this fact, we can evaluate the DE on the multivariate model using Lemma 2. Re-writing equation (20):

$$\begin{aligned} \mathbb{E}_t^\theta[\mathbf{F}\mathbf{y}_{t+1} + \mathbf{G}_1\mathbf{y}_t + \mathbf{M}\mathbf{x}_{t+1} + \mathbf{N}_1\mathbf{x}_t] &= \mathbb{E}_t[\mathbf{F}\mathbf{y}_{t+1} + \mathbf{G}_1\mathbf{y}_t + \mathbf{M}\mathbf{x}_{t+1} + \mathbf{N}_1\mathbf{x}_t] \\ &+ \theta(\mathbb{E}_t[\mathbf{F}\mathbf{y}_{t+1} + \mathbf{G}_1\mathbf{y}_t + \mathbf{M}\mathbf{x}_{t+1} + \mathbf{N}_1\mathbf{x}_t] \\ &- \mathbb{E}_{t-1}[\mathbf{F}\mathbf{y}_{t+1} + \mathbf{G}_1\mathbf{y}_t + \mathbf{M}\mathbf{x}_{t+1} + \mathbf{N}_1\mathbf{x}_t]) \end{aligned} \quad (56)$$

Using the linearity of the RE operator:

$$\begin{aligned} \mathbb{E}_t^\theta[\mathbf{F}\mathbf{y}_{t+1} + \mathbf{G}_1\mathbf{y}_t + \mathbf{M}\mathbf{x}_{t+1} + \mathbf{N}_1\mathbf{x}_t] &= \mathbf{F}\mathbb{E}_t[\mathbf{y}_{t+1}] + \mathbf{G}_1\mathbb{E}_t[\mathbf{y}_t] + \mathbf{M}\mathbb{E}_t[\mathbf{x}_{t+1}] + \mathbf{N}_1\mathbb{E}_t[\mathbf{x}_t] \\ &+ \theta(\mathbf{F}\mathbb{E}_t[\mathbf{y}_{t+1}] + \mathbf{G}_1\mathbb{E}_t[\mathbf{y}_t] + \mathbf{M}\mathbb{E}_t[\mathbf{x}_{t+1}] + \mathbf{N}_1\mathbb{E}_t[\mathbf{x}_t] \\ &- \mathbf{F}\mathbb{E}_{t-1}[\mathbf{y}_{t+1}] + \mathbf{G}_1\mathbb{E}_{t-1}[\mathbf{y}_t] + \mathbf{M}\mathbb{E}_{t-1}[\mathbf{x}_{t+1}] + \mathbf{N}_1\mathbb{E}_{t-1}[\mathbf{x}_t]) \end{aligned} \quad (57)$$

Since $\mathbb{E}_t[\mathbf{y}_t] = \mathbf{y}_t$ and $\mathbb{E}_t[\mathbf{x}_t] = \mathbf{x}_t$, and using the definitions of \mathbf{G} and \mathbf{N} in the statement of the proposition, we find that equation (18) implies equation (21).

Uniqueness follows from the fact that the DE can only be evaluated in a unique way once NNA on the multivariate model (Assumption 2) has been assumed.

Hence, model (18) is equivalent to model (21).

B Detailed Solution Procedure, Stability, and Bound- edness of the Solution: Supplementary Materials and Proofs

B.1 Detailed Solution Procedure

We solve for the recursive equilibrium law of motion of a linear diagnostic-expectations DSGE model using the method of undetermined coefficients.

Suppose that there is a unique stable solution of the model:

$$\mathbf{y}_t = \mathbf{P}\mathbf{y}_{t-1} + \mathbf{Q}\mathbf{x}_t + \mathbf{R}\mathbf{v}_t \quad (58)$$

We write the model in the rational expectations representation as

$$\begin{aligned} 0 = & \mathbf{F}\mathbf{P}^2\mathbf{y}_{t-1} + \mathbf{F}\mathbf{P}\mathbf{Q}\mathbf{x}_t + \theta\mathbf{F}\mathbf{P}\mathbf{Q}\mathbf{v}_t + (1 + \theta)\mathbf{F}\mathbf{P}\mathbf{R}\mathbf{v}_t + \mathbf{F}\mathbf{Q}\mathbf{A}\mathbf{x}_t + \theta\mathbf{F}\mathbf{Q}\mathbf{A}\mathbf{v}_t + \mathbf{G}_1\mathbf{P}\mathbf{y}_{t-1} + \dots \\ & + \mathbf{G}_1\mathbf{Q}\mathbf{x}_t + \theta\mathbf{G}_1\mathbf{Q}\mathbf{v}_t + (1 + \theta)\mathbf{G}_1\mathbf{R}\mathbf{v}_t + \mathbf{G}_2\mathbf{P}\mathbf{y}_{t-1} + \mathbf{G}_2\mathbf{Q}\mathbf{x}_t + \mathbf{G}_2\mathbf{R}\mathbf{v}_t + \mathbf{M}\mathbf{A}\mathbf{x}_t + \dots \\ & + \theta\mathbf{M}\mathbf{A}\mathbf{v}_t + \mathbf{N}_1\mathbf{x}_t + \theta\mathbf{N}_1\mathbf{v}_t + \mathbf{H}\mathbf{y}_{t-1} + \mathbf{N}_2\mathbf{x}_t \end{aligned} \quad (59)$$

It is now straightforward to proceed by the method of undetermined coefficients to find a solution of the form (58), and the matrices \mathbf{P} , \mathbf{Q} , \mathbf{R} can be found solving the following matrix equations.

$$\mathbf{F}\mathbf{P}^2 + \mathbf{G}\mathbf{P} + \mathbf{H} = 0 \quad (60)$$

$$\mathbf{F}\mathbf{P}\mathbf{Q} + \mathbf{F}\mathbf{Q}\mathbf{A} + \mathbf{G}\mathbf{Q} + \mathbf{M}\mathbf{A} + \mathbf{N} = 0 \quad (61)$$

$$\theta\mathbf{F}\mathbf{P}\mathbf{Q} + (1 + \theta)\mathbf{F}\mathbf{P}\mathbf{R} + \theta\mathbf{F}\mathbf{Q}\mathbf{A} + \theta\mathbf{G}_1\mathbf{Q} + \mathbf{G}\mathbf{R} + \theta\mathbf{G}_1\mathbf{R} + \theta\mathbf{M}\mathbf{A} + \theta\mathbf{N}_1 = 0 \quad (62)$$

where $\mathbf{G} = \mathbf{G}_1 + \mathbf{G}_2$ and $\mathbf{N} = \mathbf{N}_1 + \mathbf{N}_2$.

We can use the techniques discussed in Uhlig (1995) to solve the quadratic matrix equation (60) in \mathbf{P} . The solution of the other two equations is straightforward as they are linear in \mathbf{Q} and \mathbf{R} : After vectorization, equation (61) becomes

$$(\mathbf{I}_m \otimes \mathbf{F}\mathbf{P})\text{vec}(\mathbf{Q}) + (\mathbf{A}^T \otimes \mathbf{F})\text{vec}(\mathbf{Q}) + (\mathbf{I}_m \otimes \mathbf{G})\text{vec}(\mathbf{Q}) + \text{vec}(\mathbf{M}\mathbf{A}) + \text{vec}(\mathbf{N}) = 0 \quad (63)$$

such that

$$\text{vec}(\mathbf{Q}) = -\left((\mathbf{I}_m \otimes \mathbf{F}\mathbf{P}) + (\mathbf{A}^T \otimes \mathbf{F}) + (\mathbf{I}_m \otimes \mathbf{G}) \right)^{-1} \times (\text{vec}(\mathbf{M}\mathbf{A}) + \text{vec}(\mathbf{N})) \quad (64)$$

\mathbf{R} can be found from (62):

$$\mathbf{R} = -((1 + \theta)\mathbf{F}\mathbf{P} + \mathbf{G} + \theta\mathbf{G}_1)^{-1}(\theta\mathbf{F}\mathbf{P}\mathbf{Q} + \theta\mathbf{F}\mathbf{Q}\mathbf{A} + \theta\mathbf{G}_1\mathbf{Q} + \theta\mathbf{M}\mathbf{A} + \theta\mathbf{N}_1) \quad (65)$$

Observe that solution for matrices \mathbf{P} and \mathbf{Q} does not depend on diagnosticity parameter.

The Solution under Rational Expectations. Consider the model under rational expectations:

$$\mathbf{F}\mathbb{E}_t[\mathbf{y}_{t+1}] + \mathbf{G}\mathbf{y}_t + \mathbf{H}\mathbf{y}_{t-1} + \mathbf{M}\mathbb{E}_t[\mathbf{x}_{t+1}] + \mathbf{N}\mathbf{x}_t = 0 \quad (66)$$

where $\mathbf{G} = \mathbf{G}_1 + \mathbf{G}_2$ and $\mathbf{N} = \mathbf{N}_1 + \mathbf{N}_2$ and, as above, \mathbf{y}_t and \mathbf{x}_t denote vectors of endogenous variables (including controls and states) ($m \times 1$) and of exogenous states ($n \times 1$). \mathbb{E}_t denotes the rational expectation operator, and the exogenous process is given by (13).

Suppose that there is a unique stable solution of the model:

$$\mathbf{y}_t = \tilde{\mathbf{P}}\mathbf{y}_{t-1} + \tilde{\mathbf{Q}}\mathbf{x}_t \quad (67)$$

then, we can rewrite the stochastic difference equation (66) as follows:

$$\mathbf{F}\mathbb{E}_t[\tilde{\mathbf{P}}\mathbf{y}_t + \tilde{\mathbf{Q}}\mathbf{x}_{t+1}] + \mathbf{G}\tilde{\mathbf{P}}\mathbf{y}_{t-1} + \mathbf{G}\tilde{\mathbf{Q}}\mathbf{x}_t + \mathbf{H}\mathbf{y}_{t-1} + \mathbf{M}\mathbf{A}\mathbf{x}_t + \mathbf{N}\mathbf{x}_t = 0 \quad (68)$$

We can simplify the above equation to

$$\mathbf{F}\tilde{\mathbf{P}}^2\mathbf{y}_{t-1} + \mathbf{F}\tilde{\mathbf{P}}\tilde{\mathbf{Q}}\mathbf{x}_t + \mathbf{F}\tilde{\mathbf{Q}}\mathbf{A}\mathbf{x}_t + \mathbf{G}\tilde{\mathbf{P}}\mathbf{y}_{t-1} + \mathbf{G}\tilde{\mathbf{Q}}\mathbf{x}_t + \mathbf{H}\mathbf{y}_{t-1} + \mathbf{M}\mathbf{A}\mathbf{x}_t + \mathbf{N}\mathbf{x}_t = 0 \quad (69)$$

and can solve similarly for the recursive equilibrium law of motion via the method of undetermined coefficients. Specifically, the matrices $\tilde{\mathbf{P}}$ and $\tilde{\mathbf{Q}}$ can be found solving the following matrix equations.

$$\mathbf{F}\tilde{\mathbf{P}}^2 + \mathbf{G}\tilde{\mathbf{P}} + \mathbf{H} = 0 \quad (70)$$

$$\mathbf{F}\tilde{\mathbf{P}}\tilde{\mathbf{Q}} + \mathbf{F}\tilde{\mathbf{Q}}\mathbf{A} + \mathbf{G}\tilde{\mathbf{Q}} + \mathbf{M}\mathbf{A} + \mathbf{N} = 0 \quad (71)$$

Comparison of these equations with their counterpart under DE immediately shows that $\mathbf{P} = \tilde{\mathbf{P}}$ and $\mathbf{Q} = \tilde{\mathbf{Q}}$.

B.2 Stability

It turns out that the model under DE is subject to the same stability conditions as the model under RE. More precisely, consider the same model above, but under rational expectations ($\theta = 0$):

$$\mathbf{F}\mathbb{E}_t[\mathbf{y}_{t+1}] + \mathbf{G}\mathbf{y}_t + \mathbf{H}\mathbf{y}_{t-1} + \mathbf{M}\mathbb{E}_t[\mathbf{x}_{t+1}] + \mathbf{N}\mathbf{x}_t = 0 \quad (72)$$

where the matrices \mathbf{F} , \mathbf{G} , \mathbf{H} , \mathbf{M} and \mathbf{N} are defined above. The following result holds.

Proposition 5 (Stability) *Assume a bounded solution exists for the DE model given by equations (13) and (18). The stability conditions for this DE model are identical to the stability conditions for the RE model given by (13) and (72).*

In order to build up to the proof of this Proposition, we define a few objects. Given the quadratic matrix equation (60)

$$\mathbf{F}\mathbf{P}^2 + \mathbf{G}\mathbf{P} + \mathbf{H} = \mathbf{0} \quad (73)$$

for the $m \times m$ matrix \mathbf{P} and $m \times m$ matrices \mathbf{G} and \mathbf{H} , define the $2m \times 2m$ matrices Ξ and Δ :

$$\Xi = \begin{bmatrix} -\mathbf{G} & -\mathbf{H} \\ \mathbf{I}_m & \mathbf{0}_m \end{bmatrix} \quad (74)$$

and

$$\Delta = \begin{bmatrix} -\mathbf{F} & \mathbf{0}_m \\ \mathbf{0}_m & \mathbf{I}_m \end{bmatrix} \quad (75)$$

where \mathbf{I}_m is the identity matrix of size m and $\mathbf{0}_m$ is the $m \times m$ matrix with only zero entries.

Uhlig (1995) shows that if (a) s is a generalized eigenvector and λ is the corresponding generalized eigenvalue of Ξ with respect to Δ , then s can be written as $s' = [\lambda x', x']$ for some $x \in \mathbb{R}^m$, and (b) there are m generalized eigenvalues $\lambda_1, \dots, \lambda_m$ together with generalized eigenvectors s_1, \dots, s_m of Ξ with respect to Δ , written as $s'_i = [\lambda_i x'_i, x'_i]$ for some $x_i \in \mathbb{R}^m$, and if (x_1, \dots, x_m) is linearly dependent, then

$$\mathbf{P} = \Omega \Lambda \Omega' \quad (76)$$

is a solution to the matrix quadratic equation, where $\Omega = [x_1, \dots, x_m]$ and $\Lambda = \text{diag}(\lambda_1, \dots, \lambda_m)$.

The stability conditions are given as follows.⁴⁰

Lemma 4 *The solution \mathbf{P} is stable if $|\lambda_i| < 1$ for all $i = 1, \dots, m$.*

Thus, we can easily show that the stability conditions for both models are the same.

Proof (Proposition 5). The solutions \mathbf{P} and $\tilde{\mathbf{P}}$ are the same since they involve identical matrices \mathbf{F} , \mathbf{G} , and \mathbf{H} . Thus, the stability conditions stated in the lemma are the same for both solutions. ■

While the stability conditions are exactly same as under the RE model, we note that the existence of a bounded solution under DE requires an additional assumption. We formalize this requirement in the following proposition.

Proposition 6 (Existence of a Bounded Solution) *Assume a bounded solution exists for the RE model given by equations (13) and (18) with $\theta = 0$. Then a bounded solution for the DE model exists if $(1 + \theta)\mathbf{F}\mathbf{P} + \mathbf{G} + \theta\mathbf{G}_1$ is full-rank.*

Proof (Proposition 6). Let's consider the RE model presented in equation (66) where the exogenous variables are stacked in a $(n \times 1)$ vector \mathbf{x}_t that is assumed to follow the AR(1) stochastic process

$$\mathbf{x}_t = \mathbf{A}\mathbf{x}_{t-1} + \mathbf{v}_t \quad (77)$$

⁴⁰See Section 6.3 of Uhlig (1995) for a detailed discussion.

where \mathbf{v}_t is a $(k \times 1)$ vector of Gaussian and orthogonal exogenous shocks:

$$\mathbf{v}_t \sim N(0, \Sigma_{\mathbf{v}}) \quad (78)$$

and A is a diagonal matrix of persistence parameters.

Suppose that there is a unique stable solution of the model:

$$\mathbf{y}_t = \mathbf{P}\mathbf{y}_{t-1} + \mathbf{Q}\mathbf{x}_t \quad (79)$$

Assume, without loss of generality, that any unanticipated shocks or news only hit the economy at date 1. The economy is in steady state at date 0 or before. Then, the solution of the DE model from date 2 onwards coincides with the RE model solution. We prove this statement by considering the RE representation of the DE model derived in equation (21), reproduced here:

$$\begin{aligned} & \mathbf{F}\mathbb{E}_t[\mathbf{y}_{t+1}] + \mathbf{G}\mathbf{y}_t + \mathbf{H}\mathbf{y}_{t-1} + \mathbf{M}\mathbb{E}_t[\mathbf{x}_{t+1}] + \mathbf{N}\mathbf{x}_t \\ & \quad + \mathbf{F}\theta(\mathbb{E}_t[\mathbf{y}_{t+1}] - \mathbb{E}_{t-1}[\mathbf{y}_{t+1}]) \\ & \quad + \mathbf{M}\theta(\mathbb{E}_t[\mathbf{x}_{t+1}] - \mathbb{E}_{t-1}[\mathbf{x}_{t+1}]) \\ & \quad + \mathbf{G}_1\theta(\mathbf{y}_t - \mathbb{E}_{t-1}[\mathbf{y}_t]) \\ & \quad + \mathbf{N}_1\theta(\mathbf{x}_t - \mathbb{E}_{t-1}[\mathbf{x}_t]) = 0 \end{aligned} \quad (80)$$

Since no news or shocks are assumed to happen for $t \geq 2$, we get that

$$\mathbb{E}_t[\mathbf{y}_{t+1}] - \mathbb{E}_{t-1}[\mathbf{y}_{t+1}] = \mathbb{E}_t[\mathbf{x}_{t+1}] - \mathbb{E}_{t-1}[\mathbf{x}_{t+1}] = \mathbf{y}_t - \mathbb{E}_{t-1}[\mathbf{y}_t] = \mathbf{x}_t - \mathbb{E}_{t-1}[\mathbf{x}_t] = 0; \quad \forall t \geq 2 \quad (81)$$

The system from date $t \geq 2$ then simplifies to the RE model, the solution of which is given by equation (79) for $t \geq 2$. Date 1 solution for the DE model can then be found from (note the assumption that the economy is in steady state before date 1):

$$\begin{aligned} & \mathbf{F}\mathbb{E}_1[\mathbf{y}_2] + \mathbf{G}\mathbf{y}_1 + \mathbf{M}\mathbb{E}_1[\mathbf{x}_2] + \mathbf{N}\mathbf{x}_1 \\ & + \theta(\mathbf{F}\mathbb{E}_1[\mathbf{y}_2] + \mathbf{M}\mathbb{E}_1[\mathbf{x}_2] + \mathbf{G}_1\mathbf{y}_1 + \mathbf{N}_1\mathbf{x}_1) = 0 \end{aligned} \quad (82)$$

Notice that $\mathbb{E}_1[\mathbf{y}_2]$ and $\mathbb{E}_1[\mathbf{x}_2]$ are known at date 1 from the RE solution.

$$\mathbb{E}_1[\mathbf{y}_2] = \mathbf{P}\mathbf{y}_1 + \mathbf{Q}\mathbf{A}\mathbf{x}_1; \quad \mathbb{E}_1[\mathbf{x}_2] = \mathbf{A}\mathbf{x}_1 \quad (83)$$

After substituting these values and rearranging, we get:

$$((1 + \theta)\mathbf{FP} + \mathbf{G} + \theta\mathbf{G}_1)\mathbf{y}_1 + ((1 + \theta)(\mathbf{FQ} + \mathbf{M})\mathbf{A} + \mathbf{N} + \theta\mathbf{N}_1)\mathbf{x}_1 = 0 \quad (84)$$

Then, it follows that a bounded solution for the DE model exists if $(1 + \theta)\mathbf{FP} + \mathbf{G} + \theta\mathbf{G}_1$ is full-rank. ■

With Example 1 in Section 3, we can illustrate the result obtained in Proposition 6: When $\theta \rightarrow \frac{1}{a\phi_1} - 1$ or $\theta \rightarrow \infty$, then the DE solution explodes even though there exists a unique bounded RE solution. The lesson of this example is therefore that in practice the researcher may need to be mindful of bifurcation points. In particular, bifurcation values could affect search over the parameter space in the context of structural estimation. In our application to NK models, we compute the conditions such that the DE solution explodes, and verify that the associated limit values for θ are very large. Therefore, this does not materially affect our results.

B.3 General Condition for Extra Volatility

We establish a general result about when DE generate extra volatility over RE. Specific examples are provided in Section 4. As a reminder, in the case of DE, the solution of a general linear model takes the form:

$$\mathbf{y}_t = \mathbf{P}\mathbf{y}_{t-1} + \mathbf{Q}\mathbf{x}_t + \mathbf{R}\mathbf{v}_t \quad (85)$$

Instead, in the case of RE, the solution of model takes the form:

$$\mathbf{y}_t = \tilde{\mathbf{P}}\mathbf{y}_{t-1} + \tilde{\mathbf{Q}}\mathbf{x}_t \quad (86)$$

Comparing these two immediately leads to conjecture that, under DE, there should be extra volatility due to the presence of the extra term $\mathbf{R}\mathbf{v}_t$. However, whether this conjecture is true for a given set of parameters depends on the covariance of the matrix \mathbf{Q} with the other matrices of parameters in the solution. This is what the following proposition makes precise.

Proposition 7 (Extra Volatility) *Let \mathbf{y}_t^{DE} and \mathbf{y}_t^{RE} denote the vectors of endogenous variables under DE and RE, respectively. Let y_{it}^{DE} and y_{it}^{RE} respectively denote the i -th component of the vector of endogenous variables \mathbf{y}_t^{DE} and \mathbf{y}_t^{RE} and $\text{Var}(y_{it}^{DE})$ and $\text{Var}(y_{it}^{RE})$ denote the variance of the variable y_{it}^{DE} and of the variable y_{it}^{RE} . Then,*

$Var(y_{it}^{DE})$ is larger than $Var(y_{it}^{RE})$ if and only if:

$$diag(\mathbf{R}\Sigma_{\mathbf{v}}\mathbf{R}' + 2\mathbf{Q}\Sigma_{\mathbf{v}}\mathbf{R}')_i > 0 \quad (87)$$

where $\Sigma_{\mathbf{v}}$ is the variance-covariance matrix of \mathbf{v}_t .

Proof. We have already shown that \mathbf{P} and $\tilde{\mathbf{P}}$ are the same and that \mathbf{Q} and $\tilde{\mathbf{Q}}$ are the same. Thus, given the exogenous process \mathbf{x}_t , the solution for the model with diagnostic expectations and for the model with rational expectations can be formulated as

$$\mathbf{y}_t^{DE} = \mathbf{P}\mathbf{y}_{t-1} + \mathbf{Q}\mathbf{x}_t + \mathbf{R}\mathbf{v}_t \quad (88)$$

$$\mathbf{y}_t^{RE} = \mathbf{P}\mathbf{y}_{t-1} + \mathbf{Q}\mathbf{x}_t \quad (89)$$

such that the variance of the vector of endogenous variables under diagnostic expectations, \mathbf{y}_t^{DE} , is given by

$$\begin{aligned} Var(\mathbf{y}_t^{DE}) &= Var(\mathbf{P}\mathbf{y}_{t-1}) + Var(\mathbf{Q}\mathbf{x}_t) + Var(\mathbf{R}\mathbf{v}_t) \\ &\quad + 2 Cov(\mathbf{P}\mathbf{y}_{t-1}, \mathbf{Q}\mathbf{x}_t) + 2 Cov(\mathbf{P}\mathbf{y}_{t-1}, \mathbf{R}\mathbf{v}_t) + 2 Cov(\mathbf{Q}\mathbf{x}_t, \mathbf{R}\mathbf{v}_t) \end{aligned} \quad (90)$$

Similarly, the variance of the vector of endogenous variables under rational expectations, \mathbf{y}_t^{RE} is given by

$$Var(\mathbf{y}_t^{RE}) = Var(\mathbf{P}\mathbf{y}_{t-1}) + Var(\mathbf{Q}\mathbf{x}_t) + 2 Cov(\mathbf{P}\mathbf{y}_{t-1}, \mathbf{Q}\mathbf{x}_t) \quad (91)$$

Since $cov(\mathbf{P}\mathbf{y}_{t-1}, \mathbf{R}\mathbf{v}_t) = 0$, (90) is simplified to

$$Var(\mathbf{y}_t^{DE}) = Var(\mathbf{P}\mathbf{y}_{t-1}) + Var(\mathbf{Q}\mathbf{x}_t) + Var(\mathbf{R}\mathbf{v}_t) + 2 Cov(\mathbf{P}\mathbf{y}_{t-1}, \mathbf{Q}\mathbf{x}_t) + 2 Cov(\mathbf{Q}\mathbf{x}_t, \mathbf{R}\mathbf{v}_t) \quad (92)$$

such that by taking the difference of the two variances, we have

$$\begin{aligned} Var(\mathbf{y}_t^{DE}) - Var(\mathbf{y}_t^{RE}) &= Var(\mathbf{R}\mathbf{v}_t) + 2 Cov(\mathbf{Q}\mathbf{x}_t, \mathbf{R}\mathbf{v}_t) \\ &= Var(\mathbf{R}\mathbf{v}_t) + 2 Cov(\mathbf{Q}\mathbf{A}\mathbf{x}_{t-1} + \mathbf{Q}\mathbf{v}_t, \mathbf{R}\mathbf{v}_t) \\ &= \mathbf{R}\Sigma_{\mathbf{v}}\mathbf{R}' + 2\mathbf{Q}\Sigma_{\mathbf{v}}\mathbf{R}' \end{aligned} \quad (93)$$

Thus, for an endogenous variable y_{it} to have extra volatility with diagnostic expectations, the i -th diagonal component of the matrix $\mathbf{R}\Sigma_{\mathbf{v}}\mathbf{R}' + 2\mathbf{Q}\Sigma_{\mathbf{v}}\mathbf{R}'$ must be greater than zero. ■

We conclude by making a parallel to the work by Matsuyama (2007), who high-

lights, in the context of financial frictions, that equilibrium properties change non-monotonically with parameter values in such models. Looking at the expression for the matrix \mathbf{R} reveals that it is a non-linear function of θ . Hence, even values of θ close to zero have the potential to (discontinuously) induce large volatility in linear models.

C Diagnostic New Keynesian Model: Detailed Derivation and Proofs

There are three sets of agents in the economy: households, firms and government. Total output produced is equal to consumption expenditure made by the households and adjustment costs spent in adjusting prices.

C.1 Diagnostic Distribution

We first generalize the concept of diagnostic distribution to non-linear models with exogenous shocks.

Let \mathcal{D}_t be a vector of variables, endogenous and exogenous. Assume there is a non-linear transformation $\mathcal{D}_t \equiv \mathbf{T}(\mathcal{D}_{t-1}, \mathbf{v}_t)$, that maps time- $t - 1$ variables, \mathcal{D}_{t-1} , and a given realization of the exogenous shock process $\check{\mathbf{v}}_t$, where \mathbf{v}_t is a vector of i.i.d. exogenous Gaussian shocks $N(0, \Sigma_{\mathbf{v}})$. Notice that this can accommodate the AR(1) of exogenous variables as in Section 3. Let $f(\mathcal{D}_{t+1} | \mathcal{D}_t = \mathbf{T}(\mathcal{D}_{t-1}, \check{\mathbf{v}}_t))$ denote the true distribution of \mathcal{D}_{t+1} at time $t + 1$, conditional on current state variables. Let $f(\mathcal{D}_{t+1} | \mathcal{D}_t = \mathbf{T}(\mathcal{D}_{t-1}, \mathbb{E}_{t-1}[\mathbf{v}_t]))$ denote the true distribution of \mathcal{D}_{t+1} at time $t + 1$ conditional on a reference set of the state vector $\mathbf{T}(\mathcal{D}_{t-1}, \mathbb{E}_{t-1}[\mathbf{v}_t])$. As in the no-news assumption, the agent has not observed the current realization of the shocks \mathbf{v}_t in the reference set, and hence forms forecast of \mathcal{D}_{t+1} assuming a counterfactual path for state vector given by the expectation of the shocks. Following Maxted (2022), BGS, Gennaioli and Shleifer (2010), the “representativeness” of future states \mathcal{D}_{t+1} is given by the likelihood ratio:

$$\frac{f(\mathcal{D}_{t+1} | \mathcal{D}_t = \mathbf{T}(\mathcal{D}_{t-1}, \check{\mathbf{v}}_t))}{f(\mathcal{D}_{t+1} | \mathcal{D}_t = \mathbf{T}(\mathcal{D}_{t-1}, \mathbb{E}_{t-1}[\mathbf{v}_t]))} \quad (94)$$

Diagnostic expectations overweight states that are representative of recent news, the ones exhibiting the largest increase in likelihood based on recent information. This diagnostic distribution is formalized by assuming that agents evaluate future levels of

state vector evolve as follows:

$$f^\theta(\mathcal{D}_{t+1}|\mathcal{D}_t = \mathbf{T}(\mathcal{D}_{t-1}, \check{\mathbf{v}}_t)) = f(\mathcal{D}_{t+1}|\mathcal{D}_t = \mathbf{T}(\mathcal{D}_{t-1}, \check{\mathbf{v}}_t)) \cdot \left[\frac{f(\mathcal{D}_{t+1}|\mathcal{D}_t = \mathbf{T}(\mathcal{D}_{t-1}, \check{\mathbf{v}}_t))}{f(\mathcal{D}_{t+1}|\mathcal{D}_t = \mathbf{T}(\mathcal{D}_{t-1}, \mathbb{E}_{t-1}[\mathbf{v}_t]))} \right]^\theta \frac{1}{Z} \quad (95)$$

The extent to which representativeness distorts expectations is governed by the parameter θ .

C.2 Households

Notice that we write dynamic maximization problems, as this one, by explicitly separating time t choice variables from the expectation of future choice variables. This separation is crucial for solving the model with diagnostic expectations, and is a consequence of the DE path dependence discussed in Section 3.

Households have the following lifetime utility

$$\log C_t - \omega \frac{L_t^{1+\nu}}{1+\nu} + \mathbb{E}_t^\theta \left[\sum_{s=t+1}^\infty \beta^{s-t} \left[\log(C_s) - \frac{\omega}{1+\nu} L_s^{1+\nu} \right] \right] \quad (96)$$

subject to budget constraint:

$$P_t C_t + \frac{B_{t+1}}{(1+i_t)} = B_t + W_t L_t + D_t + T_t, \quad (97)$$

$P_t C_t$ is nominal expenditure on final consumption good, B_{t+1} denotes purchase of nominal bonds that pay off $1+i_t$ interest rate in the following period, $W_t L_t$ denotes labor income, D_t and T_t denote dividends from firm-ownership and lump-sum government transfers respectively. \mathbb{E}_t^θ is the diagnostic expectations operator with diagnosticity parameter θ .

Let $\log C_t \equiv u(C_t)$. The DE operator is the expectation over a continuous density, hence one gets these first-order conditions by taking derivatives, as usual. The consumption Euler equation is given by:

$$\frac{u'(C_t)}{P_t} = \beta(1+i_t) \mathbb{E}_t^\theta \left[\frac{u'(C_{t+1})}{P_{t+1}} \right] \quad (98)$$

Substitute the resource constraint $Y_t = C_t$, and loglinearizing:

$$\hat{y}_t = \mathbb{E}_t^\theta [\hat{y}_{t+1}] - (\hat{i}_t - (\mathbb{E}_t^\theta [\hat{p}_{t+1}] - \hat{p}_t)) \quad (99)$$

where $\{\hat{y}_t, \hat{i}_t, \hat{p}_t\}$ denote loglinear deviations of output, the nominal interest rate from their respective steady states, and of the price level from an initial price level, respectively.

Going back to (27), and computing the DE of the sum $\hat{p}_t + \hat{\pi}_{t+1}$ using the BGS formula:

$$\mathbb{E}_t^\theta[\hat{p}_{t+1}] = (1 + \theta)\mathbb{E}_t[\hat{p}_t + \hat{\pi}_{t+1}] - \theta\mathbb{E}_{t-1}[\hat{p}_t + \hat{\pi}_{t+1}] \quad (100)$$

Rearranging:

$$\mathbb{E}_t^\theta[\hat{p}_{t+1}] = \mathbb{E}_t^\theta[\hat{\pi}_{t+1}] + (1 + \theta)\hat{p}_t - \theta\mathbb{E}_{t-1}[\hat{p}_t] \quad (101)$$

Subtracting $\theta\hat{p}_{t-1}$ on both sides, we get

$$\mathbb{E}_t^\theta[\hat{p}_{t+1}] - \hat{p}_t = \mathbb{E}_t^\theta[\hat{\pi}_{t+1}] + \theta(\hat{\pi}_t - \theta\mathbb{E}_{t-1}[\hat{\pi}_t]) \quad (102)$$

which implies the diagnostic Euler equation (28).

Alternate steps to prove the equality between $(\mathbb{E}_t^\theta[\hat{p}_{t+1}] - \hat{p}_t)$ and $\mathbb{E}_t^\theta[\hat{\pi}_{t+1}] + \theta(\hat{\pi}_t - \mathbb{E}_{t-1}[\hat{\pi}_t])$ are as follows. Using the BGS formula (17) presented in the main text, we can get:

$$\mathbb{E}_t^\theta[\hat{p}_{t+1}] - \hat{p}_t = (1 + \theta)\mathbb{E}_t[\hat{p}_{t+1}] - \theta\mathbb{E}_{t-1}[\hat{p}_{t+1}] - \hat{p}_t \quad (103)$$

Adding and subtracting $(1 + \theta)\hat{p}_t$, we get:

$$\mathbb{E}_t^\theta[\hat{p}_{t+1}] - \hat{p}_t = (1 + \theta)\mathbb{E}_t[\hat{\pi}_{t+1}] - \theta\mathbb{E}_{t-1}[\hat{p}_{t+1}] + \theta\hat{p}_t \quad (104)$$

Adding and subtracting $\theta\mathbb{E}_{t-1}[\hat{p}_t]$, we get

$$\mathbb{E}_t^\theta[\hat{p}_{t+1}] - \hat{p}_t = (1 + \theta)\mathbb{E}_t[\hat{\pi}_{t+1}] - \theta\mathbb{E}_{t-1}[\hat{\pi}_{t+1}] - \theta\mathbb{E}_{t-1}[\hat{p}_t] + \theta\hat{p}_t \quad (105)$$

Adding and subtracting $\theta\hat{p}_{t-1}$, we get

$$\mathbb{E}_t^\theta[\hat{p}_{t+1}] - \hat{p}_t = (1 + \theta)\mathbb{E}_t[\hat{\pi}_{t+1}] - \theta\mathbb{E}_{t-1}[\hat{\pi}_{t+1}] + \theta(\hat{\pi}_t - \mathbb{E}_{t-1}[\hat{\pi}_t]) \quad (106)$$

Recognize that $(1 + \theta)\mathbb{E}_t[\hat{\pi}_{t+1}] - \theta\mathbb{E}_{t-1}[\hat{\pi}_{t+1}] \equiv \mathbb{E}_t^\theta[\hat{\pi}_{t+1}]$, we get that

$$\mathbb{E}_t^\theta[\hat{p}_{t+1}] - \hat{p}_t = \mathbb{E}_t^\theta[\hat{\pi}_{t+1}] + \theta(\hat{\pi}_t - \mathbb{E}_{t-1}[\hat{\pi}_t]) \quad (107)$$

Notice then that in order to loglinearize (98) one needs to take the path dependence implied by DE into consideration. Because of the reference distribution, previous beliefs held at date $t - 1$ constitute a state variable. One way to appreciate this fact

is, for instance, by looking at the BGS formula (17) and notice that the DE involves past held beliefs \mathbb{E}_{t-1} . Therefore, different from the RE case, one cannot multiply by P_t on both sides of the equation and introduce P_t inside the DE operator. Due to path dependence, computation of a real rate of interest involves the price level at $t - 1$.⁴¹ Since the agent is extrapolating from yesterday ($t - 1$) into tomorrow ($t + 1$), today's inflation innovation $\hat{\pi}_t - \mathbb{E}_{t-1}[\hat{\pi}_t]$ is also extrapolated into tomorrow when making a forecast for price level p_{t+1} : Current surprise inflation causes the diagnostic agent to expect future inflation, to a degree θ , thereby reducing the subjective real interest rate. The intuition for why this is the case is same as discussed above. Uncertainty about future variables, p_{t+1} in this instance, entails a transformation of the current variables when they enter in linear combination with future variables.

C.3 Firms

Monopolistically competitive firms, indexed by $j \in [0, 1]$, produce a differentiated good, $Y_t(j)$. We assume a Dixit-Stiglitz aggregator that aggregates intermediate goods into a final good, Y_t . Intermediate goods demand given by:

$$Y_t(j) = \left(\frac{P_t(j)}{P_t} \right)^{-\epsilon_p} Y_t \quad (109)$$

where $\epsilon_p > 1$ is the elasticity of substitution across intermediate goods' varieties, $P_t(j)$ is price of intermediate good j , and P_t is the price of final good Y_t . Each intermediate good is produced using the technology:

$$Y_t(j) = A_t L_t(j) \quad (110)$$

where $\log(A_t)$ is an aggregate TFP process that follows an AR(1) process with persistence coefficient ρ_a :

$$\log A_t = \rho_a \log A_{t-1} + \varepsilon_{a,t} \quad (111)$$

⁴¹To see this, multiply on both sides of (98) by P_{t-1} and use P_t inside the DE to obtain:

$$u'(C_t) \frac{P_{t-1}}{P_t} = \beta(1 + i_t) \mathbb{E}_t^\theta \left[u'(C_{t+1}) \frac{P_{t-1}}{P_t} \frac{P_t}{P_{t+1}} \right] \quad (108)$$

which can then be loglinearized to arrive at (28).

where $\epsilon_{a,t} \sim iid N(0, \sigma_a^2)$. Firm pays a quadratic adjustment cost in units of final good (Rotemberg 1982) to adjust prices:

$$\frac{\psi_p}{2} \left(\frac{P_t(j)}{P_{t-1}(j)} - 1 \right)^2 P_t Y_t \quad (112)$$

Firm's per period profits are given by:

$$D_t \equiv P_t(j)Y_t(j) - W_t L_t(j) - \frac{\psi_p}{2} \left(\frac{P_t(j)}{P_{t-1}(j)} - 1 \right)^2 P_t Y_t \quad (113)$$

Firm's profit maximization problem

$$\max_{P_t(j)} \left\{ P_t(j)Y_t(j) - W_t L_t(j) - \frac{\psi_p}{2} \left(\frac{P_t(j)}{P_{t-1}(j)} - 1 \right)^2 P_t Y_t + \mathbb{E}_t^\theta \left[\sum_{s=1}^{\infty} \beta^s Q_{t,t+s} D_{t+s} \right] \right\} \quad (114)$$

where $Q_{t,t+s}$ is the nominal stochastic discount factor of the household. Substitute in the demand for intermediate goods to get:

$$\max_{P_t(j)} \left\{ P_t(j) \left(\frac{P_t(j)}{P_t} \right)^{-\epsilon_p} Y_t - \frac{W_t}{A_t} \left(\frac{P_t(j)}{P_t} \right)^{-\epsilon_p} Y_t - \frac{\psi_p}{2} \left(\frac{P_t(j)}{P_{t-1}(j)} - 1 \right)^2 P_t Y_t + \mathbb{E}_t^\theta \left[\sum_{s=1}^{\infty} \beta^s Q_{t,t+s} D_{t+s} \right] \right\} \quad (115)$$

Notice that $P_t(j)$ appears in period t profits and period $t + 1$ adjustment costs. It doesn't appear anywhere else in the problem. So we can "ignore" the remaining terms as we take the first-order condition. The monopolistically competitive firm solves the following problem:

$$\begin{aligned} \max_{P_t(j)} \left\{ P_t(j) \left(\frac{P_t(j)}{P_t} \right)^{-\epsilon_p} Y_t - \frac{W_t}{A_t} \left(\frac{P_t(j)}{P_t} \right)^{-\epsilon_p} Y_t - \frac{\psi_p}{2} \left(\frac{P_t(j)}{P_{t-1}(j)} - 1 \right)^2 P_t Y_t - \mathbb{E}_t^\theta \left[\beta Q_{t,t+1} \frac{\psi_p}{2} \left(\frac{P_{t+1}(j)}{P_t(j)} - 1 \right)^2 P_{t+1} Y_{t+1} \right] \right\} \\ + \text{other terms} \end{aligned} \quad (116)$$

First order condition:

$$\begin{aligned} (1 - \epsilon_p) \left(\frac{P_t(j)}{P_t} \right)^{-\epsilon_p} Y_t + \epsilon_p \frac{W_t}{A_t P_t} \left(\frac{P_t(j)}{P_t} \right)^{-\epsilon_p - 1} Y_t - \psi_p \left(\frac{P_t(j)}{P_{t-1}(j)} - 1 \right) \frac{P_t}{P_{t-1}(j)} Y_t \\ - \psi_p \beta \mathbb{E}_t^\theta \left[\frac{u'(C_{t+1})}{u'(C_t)} \left(\frac{P_{t+1}(j)}{P_t(j)} - 1 \right) \frac{P_{t+1}(j)}{P_t(j)} \frac{P_t}{P_t(j)} Y_{t+1} \right] = 0 \end{aligned} \quad (117)$$

Symmetry across all firms implies that reset price equals the aggregate price level.

Define $\Pi_t = \frac{P_t}{P_{t-1}}$:

$$(1 - \epsilon_p)Y_t + \epsilon_p \frac{W_t}{A_t P_t} Y_t - \psi_p(\Pi_t - 1)\Pi_t Y_t + \psi_p \beta \mathbb{E}_t^\theta \left[\frac{u'(C_{t+1})}{u'(C_t)} (\Pi_{t+1} - 1)\Pi_{t+1} Y_{t+1} \right] = 0 \quad (118)$$

Divide by Y_t :

$$(1 - \epsilon_p) + \epsilon_p \frac{W_t}{A_t P_t} - \psi_p(\Pi_t - 1)\Pi_t + \frac{\psi_p}{Y_t} \beta \mathbb{E}_t^\theta \left[\frac{u'(C_{t+1})}{u'(C_t)} (\Pi_{t+1} - 1)\Pi_{t+1} Y_{t+1} \right] = 0 \quad (119)$$

Loglinearize around the deterministic steady state such that $A = 1$, $w = \frac{W}{P} = \omega C Y^\nu = \frac{\epsilon_p - 1}{\epsilon_p}$, $\Pi = 1$, and $Y_t = Y$. Let $w_t = \frac{W_t}{P_t}$

$$\epsilon_p w(\hat{w}_t - \hat{a}_t) - \psi_p \hat{\pi}_t + \psi_p \beta \mathbb{E}_t^\theta \hat{\pi}_{t+1} = 0 \quad (120)$$

Rearrange to get

$$\hat{\pi}_t = \beta \mathbb{E}_t^\theta [\hat{\pi}_{t+1}] + \frac{\epsilon_p w}{\psi_p} (\hat{w}_t - \hat{a}_t) \quad (121)$$

From the intra-temporal labor supply first order condition, we have:

$$\hat{w}_t = \hat{c}_t + \nu(\hat{y}_t - \hat{a}_t) \quad (122)$$

Use the resource constraint $\hat{c}_t = \hat{y}_t$, to rewrite the new Keynesian Phillips Curve (NKPC):

$$\hat{\pi}_t = \beta \mathbb{E}_t^\theta [\hat{\pi}_{t+1}] + \frac{\epsilon_p w}{\psi_p} (1 + \nu)(\hat{y}_t - \hat{a}_t) \quad (123)$$

Note that $\frac{\epsilon_p w}{\psi_p} = \frac{\epsilon_p - 1}{\psi_p}$. Then, the NKPC is given by

$$\hat{\pi}_t = \beta \mathbb{E}_t^\theta [\hat{\pi}_{t+1}] + \kappa(\hat{y}_t - \hat{a}_t) \quad (124)$$

where $\kappa \equiv \frac{\epsilon_p - 1}{\psi_p} (1 + \nu)$.

C.4 Policy Rule

The government sets nominal interest rate with the following rule:

$$\frac{1 + i_t}{1 + i_{ss}} = \Pi_t^{\phi_\pi} \left(\frac{Y_t}{Y_t^*} \right)^{\phi_x} \quad (125)$$

where $Y_t^* = A_t$ is the natural rate allocation, $i_{ss} = \frac{1}{\beta} - 1$ is the steady state nominal interest rate, $\phi_\pi \geq 0$, $\phi_x \geq 0$, and steady state inflation $\Pi = 1$. Loglinearized policy rule is given by:

$$\hat{i}_t = \phi_\pi \hat{\pi}_t + \phi_x (\hat{y}_t - \hat{a}_t) \quad (126)$$

We assume that nominal bonds are in net zero supply. There is no government spending.

C.5 Market Clearing

Total output produced is used for consumption expenditure.

$$Y_t = C_t \quad (127)$$

C.6 Equilibrium

We make the following assumption in order to guarantee the existence of a bounded solution (Proposition 6).⁴²

Assumption 3 (Boundedness) $\theta < \phi_\pi + \kappa^{-1}(1 + \phi_x)$

The loglinearized equilibrium in the New Keynesian model with diagnostic expectations is given by following three equations in three unknowns $\{\hat{y}_t, \hat{\pi}_t, \hat{i}_t\}$ for a given shock process $\{\hat{a}_t\}$.

$$\hat{y}_t = \mathbb{E}_t^\theta [\hat{y}_{t+1}] - (\hat{i}_t - \mathbb{E}_t^\theta [\hat{\pi}_{t+1}]) + \theta (\hat{\pi}_t - E_{t-1} [\hat{\pi}_t]) \quad (128)$$

$$\hat{\pi}_t = \beta \mathbb{E}_t^\theta [\hat{\pi}_{t+1}] + \kappa (\hat{y}_t - \hat{a}_t) \quad (129)$$

$$\hat{i}_t = \phi_\pi \hat{\pi}_t + \phi_x (\hat{y}_t - \hat{a}_t) \quad (130)$$

⁴²We also assume that $\kappa(\phi_\pi - 1) + (1 - \beta)\phi_x > 0$ to ensure a stable solution in the sense of Proposition 5.

where $\kappa \equiv \frac{\epsilon_p - 1}{\psi_p}(1 + \nu)$, and the shock processes are given by:

$$\hat{a}_t = \rho_a \hat{a}_{t-1} + \varepsilon_{a,t} \quad (131)$$

where $\varepsilon_{a,t} \sim iid N(0, \sigma_a^2)$.

Notice that we obtain a similar Phillips curve (129) to the RE case using Rotemberg (1982) pricing. The key to this result is that, different than with Calvo pricing, Rotemberg pricing with DE allows one to obtain a recursion that only involves one expectation forward. This turns out to be key for tractability. In a loglinearized RE model with perfect inflation indexation, one can obtain identical Phillips curves using either the Calvo or the Rotemberg price setting assumption.

C.7 Solution

C.7.1 Rational Expectations

Under RE, the solution of the model with TFP shocks is given by:

$$\hat{y}_t = \rho_a \frac{\phi_x(1 - \beta\rho_a) + \kappa(\phi_\pi - \rho_a)}{(1 + \phi_x - \rho_a)(1 - \beta\rho_a) + \kappa(\phi_\pi - \rho_a)} \hat{a}_{t-1} + \frac{\phi_x(1 - \beta\rho_a) + \kappa(\phi_\pi - \rho_a)}{(1 + \phi_x - \rho_a)(1 - \beta\rho_a) + \kappa(\phi_\pi - \rho_a)} \varepsilon_{a,t} \quad (132)$$

$$\hat{\pi}_t = \frac{-\rho_a \kappa(1 - \rho_a)}{(1 + \phi_x - \rho_a)(1 - \beta\rho_a) + \kappa(\phi_\pi - \rho_a)} \hat{a}_{t-1} - \frac{\kappa(1 - \rho_a)}{(1 + \phi_x - \rho_a)(1 - \beta\rho_a) + \kappa(\phi_\pi - \rho_a)} \varepsilon_{a,t} \quad (133)$$

C.7.2 Diagnostic Expectations

Guess the solution takes the following form:

$$\hat{y}_t = \alpha_1 \hat{a}_{t-1} + \gamma_1 \varepsilon_{a,t}; \quad \hat{\pi}_t = \alpha_2 \hat{a}_{t-1} + \gamma_2 \varepsilon_{a,t} \quad (134)$$

Using method of undetermined coefficients, we can solve for the coefficients. The coefficients α_1 and α_2 are identical under DE and RE.

$$\alpha_1 = \rho_a \frac{\phi_x(1 - \beta\rho_a) + \kappa(\phi_\pi - \rho_a)}{(1 + \phi_x - \rho_a)(1 - \beta\rho_a) + \kappa(\phi_\pi - \rho_a)} \quad (135)$$

$$\alpha_2 = \frac{-\rho_a \kappa(1 - \rho_a)}{(1 + \phi_x - \rho_a)(1 - \beta\rho_a) + \kappa(\phi_\pi - \rho_a)} \quad (136)$$

Coefficients γ_1 and γ_2 depend on the DE parameter.

$$\gamma_1 = \frac{(1 + \theta)\alpha_1 + (1 + \theta)\alpha_2[1 - \beta(\phi_\pi - \theta)] + \kappa(\phi_\pi - \theta)}{1 + \phi_x + \kappa(\phi_\pi - \theta)}; \quad \gamma_2 = \beta(1 + \theta)\alpha_2 + \kappa(\gamma_1 - 1) \quad (137)$$

C.8 Proof of Propositions 2 and 3

Because there are no government shocks, $\hat{c}_t = \hat{y}_t$. The equilibrium with completely rigid prices, i.e. $\psi_p \rightarrow \infty$, given by:

$$\hat{y}_t = \mathbb{E}_t^\theta [\hat{y}_{t+1}] - \hat{i}_t \quad (138)$$

$$\hat{i}_t = \phi_x(\hat{y}_t - \hat{a}_t) \quad (139)$$

where $\hat{a}_t = \rho_a \hat{a}_{t-1} + \varepsilon_{a,t}$, $\rho_a \in [0, 1)$, and $\varepsilon_{a,t} \sim iid N(0, \sigma_a^2)$. Substituting the policy rule into the Euler equation, we get:

$$\hat{y}_t = \frac{1}{1 + \phi_x} \mathbb{E}_t^\theta [\hat{y}_{t+1}] + \frac{\phi_x}{1 + \phi_x} \hat{a}_t \quad (140)$$

By forward iteration, and using the law of iterated expectations under the no-news assumption,

$$\hat{y}_t = \lim_{T \rightarrow \infty} \frac{\mathbb{E}_t^\theta [\hat{y}_{T+1}]}{(1 + \phi_x)^{T+1}} + \sum_{i=1}^{\infty} \frac{\phi_x \mathbb{E}_t^\theta [\hat{a}_{t+i}]}{(1 + \phi_x)^{i+1}} + \frac{\phi_x}{1 + \phi_x} \hat{a}_t \quad (141)$$

The system is locally determinate if and only if $\phi_x > 0$. Let $\phi_x > 0$. Then,

$$\hat{y}_t = \sum_{i=1}^{\infty} \frac{\phi_x \mathbb{E}_t^\theta [\hat{a}_{t+i}]}{(1 + \phi_x)^{i+1}} + \frac{\phi_x}{1 + \phi_x} \hat{a}_t \quad (142)$$

From the definition of the shock process, we know that, $\forall i > 0$

$$\mathbb{E}_t^\theta [\hat{a}_{t+i}] = \rho_a^i (1 + \theta) \hat{a}_t - \theta \rho_a^{i+1} \hat{a}_{t-1} = \rho_a^i ((1 + \theta) \hat{a}_t - \theta \rho_a \hat{a}_{t-1}) \quad (143)$$

We can then derive the solution for output:

$$\hat{y}_t = \frac{\phi_x \rho_a (1 + \theta) + \phi_x (1 + \phi_x - \rho_a)}{(1 + \phi_x)(1 + \phi_x - \rho_a)} \hat{a}_t - \frac{\phi_x \theta \rho_a^2}{(1 + \phi_x)(1 + \phi_x - \rho_a)} \hat{a}_{t-1} \quad (144)$$

This solution can be rewritten as:

$$\hat{y}_t = \rho \frac{\phi_x(1 + \phi_x)}{(1 + \phi_x)(1 + \phi_x - \rho_A)} \hat{a}_{t-1} + \frac{\phi_x \rho_A \theta + \phi_x(1 + \phi_x)}{(1 + \phi_x)(1 + \phi_x - \rho_A)} \varepsilon_{a,t} \quad (145)$$

Volatility of output is then

$$Var(\hat{y}_t) = \left(\rho \frac{\phi_x(1 + \phi_x)}{(1 + \phi_x)(1 + \phi_x - \rho_A)} \right)^2 Var(\hat{a}_{t-1}) + \left(\frac{\phi_x \rho_A \theta + \phi_x(1 + \phi_x)}{(1 + \phi_x)(1 + \phi_x - \rho_A)} \right)^2 \sigma^2 \quad (146)$$

The first coefficient is same under rational and diagnostic expectations. Volatility is higher under diagnostic expectations relative to rational expectations if and only if

$$(\phi_x \rho_A \theta + \phi_x(1 + \phi_x))^2 > \phi_x^2(1 + \phi_x)^2 \quad (147)$$

$$\iff \theta > 0 \quad (148)$$

In the flexible price limit, $\kappa \rightarrow \infty$, output under DE and RE follows (from C.7):

$$\hat{y}_t = \rho_a \hat{a}_{t-1} + \varepsilon_{a,t} \equiv \hat{a}_t \quad (149)$$

Hence, DE and RE have the same output variability when $\kappa \rightarrow \infty$ (or $\psi_p \rightarrow 0$).

This completes the proof for Proposition 2.

The solution for output gap $\hat{x}_t \equiv \hat{y}_t - \hat{a}_t$ is given by:

$$\hat{x}_t = \frac{-\rho_a(1 - \rho_a)(1 + \phi_x)}{(1 + \phi_x)(1 + \phi_x - \rho_a)} \hat{a}_{t-1} + \frac{\theta \phi_x \rho_a - (1 - \rho_a)(1 + \phi_x)}{(1 + \phi_x)(1 + \phi_x - \rho_a)} \varepsilon_{a,t} \quad (150)$$

which can also be written as

$$\hat{x}_t = \frac{\phi_x \rho_a(1 + \theta) - (1 + \phi_x - \rho_a)}{(1 + \phi_x)(1 + \phi_x - \rho_a)} \hat{a}_t - \frac{\phi_x \theta \rho_a^2}{(1 + \phi_x)(1 + \phi_x - \rho_a)} \hat{a}_{t-1} \quad (151)$$

When $\theta > 0$, the second term denotes the reversal from revision in expectations.

In response to an unanticipated improvement in productivity, output gap can be positive on impact if and only

$$\theta \phi_x \rho_a - (1 - \rho_a)(1 + \phi_x) > 0 \quad (152)$$

When $\theta = 0$, that is rational expectations, output gap negatively co-moves with productivity shock. Under diagnostic expectations, productivity improvements can be expansionary on impact. This completes the proof for Proposition 3.

C.9 Proof of Proposition 4

Note that after a one-time unanticipated shock, the solution under DE and RE coincide at subsequent dates since there is no news. (This was shown formally in the context of the general linear model in the previous appendix, proof of Proposition 6.) At date $t = 1$, we can derive the solution under DE as follows. From the RE solution, we know the expectations of forward looking variables :

$$\mathbb{E}_1 \hat{y}_2 = \rho_g \frac{(1 - \beta \rho_g)(1 - \rho_g) + \kappa \psi (\phi_\pi - \rho_g)}{(1 - \beta \rho_g)(1 - \rho_g + \phi_x) + \kappa (\phi_\pi - \rho)} \varepsilon_{g,t}; \quad (153)$$

$$\mathbb{E}_1 \hat{\pi}_2 = \rho_g \frac{\kappa(1 - \psi)(1 - \rho_g) - \kappa \psi \phi_x}{(1 - \beta \rho_g)(1 - \rho_g + \phi_x) + \kappa (\phi_\pi - \rho_g)} \varepsilon_{g,t} \quad (154)$$

$$\mathbb{E}_0 \hat{y}_2 = \mathbb{E}_0 \hat{\pi}_2 = \mathbb{E}_0 \hat{\pi}_1 = 0 \quad (155)$$

We can thus construct the diagnostic expectation terms that enter the DE model, and simplify the model to

$$\hat{y}_1 = (1 + \theta) \mathbb{E}_1 [\hat{y}_2 + \hat{\pi}_2 - \hat{g}_2] - \hat{i}_1 + \theta \hat{\pi}_1 + \hat{g}_1 \quad (156)$$

$$\hat{\pi}_1 = \beta(1 + \theta) \mathbb{E}_1 [\hat{\pi}_2] + \kappa \hat{y}_1 - \kappa \psi \hat{g}_1 \quad (157)$$

$$\hat{i}_1 = \phi_\pi \hat{\pi}_1 + \phi_x \hat{y}_1 \quad (158)$$

Substituting the latter two equations into the Euler equation, and rearranging we get

$$\hat{y}_1 = \frac{(1 + \theta) \mathbb{E}_1 [\hat{y}_2 + (1 + \beta \theta - \beta \phi_\pi) \hat{\pi}_2] + [1 + (\phi_\pi - \theta) \kappa \psi - (1 + \theta) \rho_g] \varepsilon_{g,1}}{1 + \phi_x + (\phi_\pi - \theta) \kappa} \quad (159)$$

The corresponding RE solution can be seen with $\theta = 0$.

We study three scenarios with analytical results:

1. When the shocks are iid ($\rho_g = 0$), the solution is:

$$\hat{y}_1 = \frac{1 + (\phi_\pi - \theta) \kappa \psi}{1 + \phi_x + (\phi_\pi - \theta) \kappa} \varepsilon_{g,1} \quad (160)$$

For a bounded solution (and continuity with RE solution), we assume that $\theta < \phi_\pi + \kappa^{-1}(1 + \phi_x)$. There are two cases for the fiscal multiplier:

- $\phi_x < \nu$: The fiscal multiplier under DE is larger than under RE. The multiplier is increasing in θ , exceeds one for values of $\theta > \phi_\pi + \frac{\phi_x}{(1 - \psi)\kappa}$. As $\theta \rightarrow \phi_\pi + \kappa^{-1}(1 + \phi_x)$, the fiscal multiplier $\rightarrow \infty$.
- $\phi_x > \nu$: The fiscal multiplier under DE is smaller than under RE.

2. When the government spending shocks are iid and $\phi_x = 0$, the solution for output under DE is :

$$\hat{y}_1 = \frac{1 + (\phi_\pi - \theta)\kappa\psi}{1 + (\phi_\pi - \theta)\kappa} \varepsilon_{g,1} \quad (161)$$

For the solution to be continuous in the RE limit and bounded, we assume that $\theta < \phi_\pi + \kappa^{-1}$. Since $\psi = \frac{1}{1+\nu} < 1$, the fiscal multiplier is increasing in θ . Under the RE limit, $\theta = 0$, the fiscal multiplier is strictly less than one. For $\theta > \phi_\pi$, the multiplier is larger than one. Finally, the multiplier explodes to infinity as $\theta \rightarrow \phi_\pi + \kappa^{-1}$.

3. When prices are perfectly rigid, that is $\kappa \rightarrow 0$, the solution for output is given by:

$$\hat{y}_1 = \frac{(1 - \rho_g)(1 + \phi_x) - \theta\rho_g\phi_x}{(1 + \phi_x)(1 - \rho_g + \phi_x)} \varepsilon_{g,1} \quad (162)$$

Fiscal multiplier under DE is smaller than under RE. Fiscal multiplier is decreasing in θ . For $\theta > \frac{(1-\rho_g)(1+\phi_x)}{\rho_g\phi_x}$, assuming $\rho_g > 0$, output falls under DE with increase in government spending.

D Real Business Cycle Model

We list the equilibrium conditions for a standard RBC model. Equilibrium is given by a sequence of seven unknowns $\{C_t, K_{t+1}, Y_t, I_t, N_t, R_t^k, \tilde{W}_t\}$ that satisfy the following seven equations for a given exogenous process A_t and an initial value of capital stock K_0 .

$$\frac{1}{C_t} = \beta \mathbb{E}_t^\theta \left[\frac{R_{t+1}^k + 1 - \delta}{C_{t+1}} \right] \quad (163)$$

$$\tilde{W}_t = \omega C_t N_t^\nu \quad (164)$$

$$K_{t+1} = (1 - \delta)K_t + I_t \quad (165)$$

$$Y_t = K_t^\alpha (A_t N_t)^{1-\alpha} \quad (166)$$

$$Y_t = C_t + I_t \quad (167)$$

$$R_t^k = \alpha \frac{Y_t}{K_t} \quad (168)$$

$$\tilde{W}_t = (1 - \alpha) \frac{Y_t}{N_t} \quad (169)$$

β is the discount rate, δ is depreciation rate, ν is inverse of the Frisch elasticity of labor supply, α is the capital share, and ω is a normalizing constant in the steady state. $\theta > 0$ is the diagnosticity parameter. The system of loglinearized equations is as follows (where the lower case letters denote the log-deviations from the respective steady state values)⁴³:

$$\tilde{w}_t = c_t + \nu n_t \quad (170)$$

$$c_t = \mathbb{E}_t^\theta \left[c_{t+1} - \frac{R^k}{R^k + 1 - \delta} r_{t+1}^k \right] \quad (171)$$

$$k_{t+1} = \delta \hat{I}_t + (1 - \delta) k_t \quad (172)$$

$$y_t = (1 - \alpha) a_t + \alpha k_t + (1 - \alpha) n_t \quad (173)$$

$$y_t = s_c c_t + (1 - s_c) \hat{I}_t \quad (174)$$

$$r_t^k = y_t - k_t \quad (175)$$

$$\tilde{w}_t = y_t - n_t \quad (176)$$

where R^k is the steady state rental rate, and s_c is the steady state share of consumption in output. The economy starts in the steady state. There is a one-time unanticipated iid shock a_1 at time 1.

D.1 Rational Expectations and Full Depreciation, $\delta = 1$

We derive analytical result assuming full depreciation, that is $\delta = 1$. The Euler equation under rational expectations and full depreciation is given by:

$$c_t - k_{t+1} = \mathbb{E}_t [c_{t+1} - y_{t+1}] \quad (177)$$

From the labor supply and labor demand conditions, we obtain

$$(1 + \nu) n_t = y_t - c_t \quad (178)$$

When $\delta = 1$, $\hat{I}_t = k_{t+1}$. Use the above equation into the Euler equation, along with investment equation to get

$$\hat{I}_t - y_t + (1 + \nu) n_t = (1 + \nu) \mathbb{E}_t [n_{t+1}] \quad (179)$$

⁴³ \hat{I}_t is also log-deviations of investment I_t from its steady state value.

Substitute in the resource constraint,

$$\frac{1}{1-s_c} [y_t - s_c c_t] - y_t + (1+\nu)n_t = (1+\nu)\mathbb{E}_t[n_{t+1}] \quad (180)$$

$$\iff \frac{s_c}{1-s_c} [y_t - c_t] + (1+\nu)n_t = (1+\nu)\mathbb{E}_t[n_{t+1}] \quad (181)$$

$$\iff \left(1 + \frac{s_c}{1-s_c}\right) n_t = \mathbb{E}_t[n_{t+1}] \quad (182)$$

Solution for employment is

$$n_t = 0, \quad \forall t \geq 0 \quad (183)$$

We can solve for the solution for other variables at dates 1 and 2:

$$c_1 = y_1 = \hat{I}_1 = k_2 = (1-\alpha)a_1; \quad (184)$$

$$c_2 = y_2 = \hat{I}_2 = k_3 = \alpha(1-\alpha)a_1 \quad (185)$$

and so on.

D.2 Diagnostic Expectations and full depreciation, $\delta = 1$

The Euler equation is

$$c_t = \mathbb{E}_t^\theta [c_{t+1} - y_{t+1} + k_{t+1}] \quad (186)$$

As before, the economy starts in the steady state. There is a one-time unanticipated iid shock a_1 at time 1. From Date 2, the solution is same as rational expectations model. Since, we have iid shocks, the solution at date 1 is:

$$c_1 = (1+\theta)k_2 \quad (187)$$

Substitute into the resource constraint to get

$$y_1 = (1+\theta s_c)k_2 \quad (188)$$

From labor supply and labor demand,

$$(1+\nu)n_1 = y_1 - c_1 = -\theta(1-s_c)k_2 \quad (189)$$

Finally, from the production function

$$y_1 = (1 - \alpha)a_1 + (1 - \alpha)n_1 \quad (190)$$

$$\iff (1 + \theta s_c)k_2 = (1 - \alpha)a_1 + (1 - \alpha)n_1 \quad (191)$$

$$\iff -\frac{(1 + \theta s_c)}{\theta(1 - s_c)}(1 + \nu)n_1 = (1 - \alpha)a_1 + (1 - \alpha)n_1 \quad (192)$$

$$n_1 = -\frac{\theta(1 - s_c)(1 - \alpha)a_1}{(1 + \theta s_c)(1 + \nu) + (1 - \alpha)\theta(1 - s_c)} \quad (193)$$

Solution is

$$n_1 = -\frac{\theta(1 - s_c)(1 - \alpha)a_1}{(1 + \theta s_c)(1 + \nu) + (1 - \alpha)\theta(1 - s_c)} \quad (194)$$

$$k_2 = \frac{(1 - \alpha)(1 + \nu)a_1}{(1 + \theta s_c)(1 + \nu) + (1 - \alpha)\theta(1 - s_c)} \quad (195)$$

$$c_1 = \frac{(1 + \theta)(1 - \alpha)(1 + \nu)a_1}{(1 + \theta s_c)(1 + \nu) + (1 - \alpha)\theta(1 - s_c)} \quad (196)$$

$$y_1 = \frac{(1 + \theta s_c)(1 - \alpha)(1 + \nu)a_1}{(1 + \theta s_c)(1 + \nu) + (1 - \alpha)\theta(1 - s_c)} \quad (197)$$

Date 2 solution is :

$$n_2 = 0 \quad (198)$$

$$y_2 = \alpha k_2 = \frac{\alpha(1 - \alpha)(1 + \nu)a_1}{(1 + \theta s_c)(1 + \nu) + (1 - \alpha)\theta(1 - s_c)} \quad (199)$$

D.3 Analytical Proposition for RBC model

Proposition 8 (Extra Volatility: RBC Model) *Consider the model given by (131), (170)-(176). Assume that the depreciation rate $\delta = 1$ and that $\rho_a = 0$. Output is less volatile under DE than under RE: $Var(\hat{y}_t)_{DE} < Var(\hat{y}_t)_{RE}$.*

Volatility of output at date 1 is lower under DE compared to RE if and only if

$$\frac{(1 + \theta s_c)(1 + \nu)}{(1 + \theta s_c)(1 + \nu) + (1 - \alpha)\theta(1 - s_c)} < 1 \quad (200)$$

which is true. Further, note that volatility of output at date 1 under DE is decreasing in ν . Similarly, we can show that volatility of output under diagnostic expectations is lower at all future horizons as well. For example, Volatility of output at date 2 is

lower under DE compared to RE if and only if

$$\frac{(1 + \nu)}{(1 + \theta s_c)(1 + \nu) + (1 - \alpha)\theta(1 - s_c)} < 1 \quad (201)$$

which is true since $1 + \theta s_c > 1$ and $(1 - \alpha)\theta(1 - s_c) > 0$.

D.4 Numerical Results on Extra Volatility: NK and RBC Models

To numerically demonstrate the excess volatility in the NK model, we use the calibration discussed in Table 4, which is our standard calibration. Stationary TFP follows an AR(1) process with persistence 0.9 and standard deviation 0.02. We set the discount factor β to 0.99. For the RBC model, we set the capital share α to 0.2 and the capital depreciation rate δ to 0.025. For the NK model, we set $\phi_\pi = 1.5$, $\phi_x = 0.5$, and $\kappa = 0.05$. We also set the diagnosticity parameter θ to one.

Table 4: Calibration: The NK and RBC models

	Parameter	Value
<i>Common to Both Models</i>		
θ	Diagnosticity	1
β	Discount factor	0.99
<i>NK model</i>		
ν	Inv. Frisch elasticity	2
ϕ_π	Taylor rule inflation	1.5
ϕ_x	Taylor rule output gap	0.5
κ	Slope of the Phillips curve	0.05
<i>RBC model</i>		
α	Capital share	0.2
δ	Capital depreciation rate	0.025
<i>Shock Process</i>		
ρ_a	Shock persistence (stationary TFP)	0.9
σ_a	Standard dev. (stationary TFP)	0.02

Notes: The NK model is given by (128) to (130) and the RBC model is given by (170) to (176). The shock process is given by (131).

Panel a) in Table 5 shows unconditional volatilities of output growth, and consump-

Table 5: Model-Implied Volatilities with Stationary TFP Shocks

(a) New Keynesian Model			
Variable	Rational Expectations	Diagnostic Expectations	Percentage Increase
Output	0.0182	0.0296	63%
Consumption	0.0182	0.0296	63%
Investment	–	–	–
(b) Real Business Cycle Model			
Variable	Rational Expectations	Diagnostic Expectations	Percentage Increase
Output	0.0204	0.0188	-8%
Consumption	0.0052	0.0103	96%
Investment	0.1147	0.0816	-29%

Notes: The table reports the standard deviations of output growth, consumption growth and investment growth in the New Keynesian (NK) model and the RBC model in Panels (a) and (b) respectively. Final column titled “Percentage Increase” shows the percentage increase in standard deviation under the diagnostic expectations model relative to the rational expectations benchmark. There is one shock process in the two models. See Table 4 for the parameters.

tion growth under diagnostic and rational expectations. Since there is no government spending or investment, output growth and consumption growth are equivalent in the NK model. We find that the output gap under diagnostic expectations exhibits 63 percent higher standard deviation relative to the output gap under rational expectations.

Panel b) in Table 5 shows unconditional volatilities of output growth, consumption growth, and investment growth, both under diagnostic and rational expectations in the baseline RBC model. Consumption growth is twice as volatile under diagnostic expectations than under rational expectations. On the other hand, investment growth and output growth are dampened under diagnostic expectations due to the general equilibrium adjustment of the interest rate. Diagnosticity, therefore, does not always generate extra amplification.

E A Medium-Scale DSGE model

E.1 Model Ingredients

The model follows the exposition in BLL. The economy comprises of following agents: a continuum of households supplying differentiated labor, a continuum of firms producing differentiated goods, a perfectly competitive final goods firm, a perfectly competitive labor agency that provides the composite labor input demanded by firms, and a government in charge of fiscal and monetary policy.

E.1.1 Monopolistically Competitive Producers

Assume there is a continuum of differentiated intermediate good producers that sell the intermediate good Y_{jt} . A perfectly competitive firm aggregates intermediate goods into a final composite good $Y_t = \left[\int_0^1 Y_{jt}^{\frac{\epsilon_{p,t}-1}{\epsilon_{p,t}}} dj \right]^{\frac{\epsilon_{p,t}}{\epsilon_{p,t}-1}}$, where $\epsilon_{p,t} > 1$ is time-varying elasticity of demand and denote the time-varying price markup with $\lambda_t^p = \frac{\epsilon_{p,t}}{\epsilon_{p,t}-1}$. The iso-elastic demand for intermediate good j is given by: $Y_{jt} = \left(\frac{P_{jt}}{P_t} \right)^{-\epsilon_{p,t}} Y_t$, where P_t is the aggregate price index and P_{jt} is the price of intermediate goods j . Each intermediate good j is produced by a price-setting monopolistically competitive firm using labor L_{jt} and physical capital K_{jt} :

$$Y_{jt} = (A_t L_{jt})^{1-\alpha} K_{jt}^\alpha \quad (202)$$

where the TFP process A_t is the sum of two components (in logs):

$$\log A_t = \log Z_t + \log \Xi_t \quad (203)$$

The variable Z_t denotes a non-stationary TFP series that evolves according to:

$$\frac{Z_t}{Z_{t-1}} = \left(\frac{Z_{t-1}}{Z_{t-2}} \right)^{\rho_\zeta} G_\zeta^{1-\rho_\zeta} \exp(\varepsilon_{\zeta,t}); \quad \varepsilon_{\zeta,t} \sim iid N(0, \sigma_\zeta^2) \quad (204)$$

where ρ_ζ is the persistence of the shock process, and $\varepsilon_{\zeta,t}$ is a random disturbance that causes deviations of the TFP growth from its balanced growth rate G_ζ . The stationary TFP evolves as follows:

$$\log \Xi_t = \rho_\xi \log \Xi_{t-1} + \varepsilon_{\xi,t}; \quad \varepsilon_{\xi,t} \sim iid N(0, \sigma_\xi^2) \quad (205)$$

where ρ_ξ is the persistence of the shock process, and $\varepsilon_{\xi,t}$ is an i.i.d shock with variance σ_ξ^2 . (We define $a_t \equiv \log A_t$, $\zeta_t \equiv \log Z_t$, $\xi_t \equiv \log \Xi_t$, $G_{a,t} \equiv A_t/A_{t-1}$, and $G_{\zeta,t} \equiv Z_t/Z_{t-1}$.)

Following BLL, we assume that

$$\rho_\zeta = \rho_\xi \equiv \rho \quad (206)$$

and that the variances satisfy the following restriction⁴⁴

$$\rho\sigma_\zeta^2 = (1 - \rho)^2\sigma_\xi^2 \quad (207)$$

While agents observe the TFP process as a whole, they do not observe two components ζ_t and ξ_t separately. Considering the idea that agents have more information than merely about productivity, agents observe a noisy signal s_t about the permanent component of TFP:

$$s_t = \zeta_t + \varepsilon_{s,t}; \quad \varepsilon_{s,t} \sim iid N(0, \sigma_s^2) \quad (208)$$

where $\varepsilon_{s,t}$ is an i.i.d. normal shock, which affects agents' beliefs but is independent of fundamentals. This noisy signal relates to the additional informative signal that agents receive which is a straightforward interpretation of Equation (208). Ultimately, the presence of this noisy information helps the econometrician make inferences about the (unobserved) long-term productivity trend by looking at the behavior of consumption.

Firms choose inputs to minimize total cost each period. Marginal cost, independent of firm-specific variables, is given by $mc_t = \frac{1}{A_t^{1-\alpha}} \left(\frac{R_t^k/P_t}{\alpha} \right)^\alpha \left(\frac{W_t/P_t}{1-\alpha} \right)^{1-\alpha}$, where $\frac{R_t^k}{P_t}$ and $\frac{W_t}{P_t}$ denote aggregate rental rate of capital and real wage. A firm j pays a quadratic adjustment cost in units of final good (Rotemberg 1982) to adjust its price P_{jt} . The cost is given by $\frac{\psi_p}{2} \left(\frac{P_{jt}}{\bar{\Pi}_{t-1}P_{jt-1}} - 1 \right)^2 P_t Y_t$, where $\psi_p \geq 0$ regulates the adjustment costs. Price change is indexed to $\tilde{\Pi}_{t-1} = \bar{\Pi}^{1-\iota_p} \Pi_{t-1}^{\iota_p}$, where ι_p governs indexation between previous period inflation rate Π_{t-1} and steady state inflation rate $\bar{\Pi}$. Firm's per period profits are given by: $D_{jt} \equiv P_{jt}Y_{jt} - P_t mc_t Y_{jt} - \frac{\psi_p}{2} \left(\frac{P_{jt}}{\bar{\Pi}_{t-1}P_{jt-1}} - 1 \right)^2 P_t Y_t$. Each period, the firm chooses P_{jt} to maximize present discounted value of real profits:

$$\max_{P_{jt}} \left\{ \frac{\Lambda_t D_{jt}}{P_t} + \mathbb{E}_t^\theta \left[\sum_{s=1}^{\infty} \frac{\Lambda_{t+s} D_{jt+s}}{P_{t+s}} \right] \right\} \quad (209)$$

where Λ_t is the marginal utility of consumption in period t , and $\mathbb{E}_t^\theta[\cdot]$ is the diagnostic expectation operator regulated by parameter θ . Notice that we write dynamic maximization problems by explicitly separating time t choice variables from the expectation of future choice variables. This separation is crucial for solving the model with diagnostic expectations, and is a consequence of the technical issues discussed in Section 3.

⁴⁴As shown in BLL, these restrictions imply that the univariate process for a_t is a random walk with variance σ_a^2 .

E.1.2 Households

There is a continuum of monopolistically competitive households, indexed by $i \in [0, 1]$, supplying a differentiated labor input $L_{i,t}$. A perfectly competitive employment agency aggregates various labor types into a composite labor input L_t supplied to firms, in a Dixit-Stiglitz aggregator: $L_t = \left[\int_0^1 L_{i,t}^{\frac{\epsilon_{w,t}-1}{\epsilon_{w,t}}} di \right]^{\frac{\epsilon_{w,t}}{\epsilon_{w,t}-1}}$, where $\epsilon_{w,t} > 1$ is time-varying elasticity of demand. Define $\lambda_t^w = \frac{\epsilon_{w,t}}{\epsilon_{w,t}-1}$ as time-varying wage markup. The iso-elastic demand for labor input i is given by: $L_{i,t} = \left(\frac{W_{i,t}}{W_t} \right)^{-\epsilon_{w,t}} L_t$, where $W_{i,t}$ is household i 's wage rate, and W_t is the aggregate wage rate that the household takes as given.

The household i has following lifetime-utility at time t :

$$\left(\log(C_{i,t} - h\tilde{C}_{t-1}) - \frac{\omega}{1+\nu} L_{i,t}^{1+\nu} - \psi_{i,t}^w \right) + \mathbb{E}_t^\theta \left[\sum_{s=t+1}^\infty \beta^{s-t} \left(\log(C_{i,s} - h\tilde{C}_{s-1}) - \frac{\omega}{1+\nu} L_{i,s}^{1+\nu} - \psi_{i,s}^w \right) \right] \quad (210)$$

where h is the degree of habit formation on external habits over aggregate consumption \tilde{C}_{t-1} , which the household takes as given, $\nu > 0$ is inverse of the Frisch elasticity of labor supply, $\omega > 0$ is a parameter that pins down the steady-state level of hours, and the discount factor β satisfies $0 < \beta < 1$. $\psi_{i,t}^w$ is the loss in utility in adjusting wages. We assume a quadratic adjustment cost given by $\psi_{i,t}^w = \frac{\psi_w}{2} \left[\frac{W_{i,t}}{\tilde{\Pi}_{t-1}^w W_{i,t-1}} - 1 \right]^2$, where $\psi_w \geq 0$ is a parameter, and wage contracts are indexed to productivity and price inflation. We assume $\tilde{\Pi}_{t-1}^w = G_a \bar{\Pi}^{1-\iota_w} (\exp(\varepsilon_{\zeta,t} \varepsilon_{\xi,t}) \Pi_{t-1})^{\iota_w}$ with $0 \leq \iota_w < 1$.

The household's budget constraint in period t is given by

$$P_t C_{i,t} + P_t I_{i,t} + \frac{B_{i,t+1}}{1+i_t} = B_{i,t} + W_{i,t} L_{i,t} + D_t + T_t + R_t^K u_{i,t} K_{i,t}^u - P_t a(u_{i,t}) K_{i,t}^u \quad (211)$$

where $I_{i,t}$ is investment, $W_{i,t} L_{i,t}$ is labor income, and $B_{i,t}$ is income from nominal bonds paying nominal interest rate i_t . Households own an equal share of all firms, and thus receive D_t dividends from profits. Finally, each household receives a lump-sum government transfer T_t .

The households own capital, $K_{i,t}^u$, and choose the utilization rate, $u_{i,t}$. The amount of effective capital, $K_{i,t}$, that the households rent to the firms at nominal rate R_t^K is given by $K_{i,t} = u_{i,t} K_{i,t}^u$. The (nominal) cost of capital utilization is $P_t \chi(u_{i,t})$ per unit of physical capital. As in the literature, we assume $\chi(1) = 0$ in the steady state and $\chi'' > 0$. Following GHLS, we assume investment adjustment costs, $S \left(\frac{I_{i,t}}{G_a I_{i,t-1}} \right)$, in the production of capital, where G_a is the steady state growth rate of A_t . Law of motion

for capital is as follows:

$$K_{i,t+1}^u = \mu_t \left[1 - S \left(\frac{I_{i,t}}{G_a I_{i,t-1}} \right) \right] I_{i,t} + (1 - \delta_k) K_{i,t}^u \quad (212)$$

where δ_k denotes depreciation rate, and μ_t is an exogenous disturbance to the marginal efficiency of investment that follows:

$$\log \mu_t = \rho_\mu \log \mu_{t-1} + \varepsilon_{\mu,t}; \quad \varepsilon_{\mu,t} \sim iid N(0, \sigma_\mu^2) \quad (213)$$

As in the literature, we assume that $S(1) = S'(1) = 0$, and calibrate $S''(1) > 0$.

E.1.3 Government

The central bank follows a Taylor rule in setting the nominal interest rate i_t . It responds to deviations in (gross) inflation rate Π_t from its target rate $\bar{\Pi}$ and output.

$$\frac{1 + i_t}{1 + i_{ss}} = \left(\frac{1 + i_{t-1}}{1 + i_{ss}} \right)^{\rho_R} \left[\left(\frac{\Pi_t}{\bar{\Pi}} \right)^{\phi_\pi} Y_t^{\phi_y} \right]^{1-\rho_R} \exp(\lambda_t^{mp}) \quad (214)$$

with $0 < \rho_R < 1$, $\phi_\pi \geq 0$, and $\phi_y \geq 0$. i_{ss} is the steady state nominal interest rate, and λ_t^{mp} follows the process

$$\log \lambda_t^{mp} = \rho_{mp} \log \lambda_{t-1}^{mp} + \varepsilon_{mp,t}; \quad \varepsilon_{mp,t} \sim N(0, \sigma_{mp}^2) \quad (215)$$

We assume government balances budget every period $P_t T_t = P_t G_t$, where G_t is the government spending. G_t is determined exogenously as a fraction of GDP: $G_t = \left(1 - \frac{1}{\lambda_t^g}\right) Y_t$ where the government spending shock follows the process:

$$\log \lambda_t^g = (1 - \rho_g) \log \lambda^g + \rho_g \log \lambda_{t-1}^g + \varepsilon_{g,t}; \quad \varepsilon_{g,t} \sim N(0, \sigma_g^2) \quad (216)$$

λ^g is the steady state share of government spending in final output.

E.1.4 Market Clearing

We focus on a symmetric equilibrium where all intermediate goods producing firms and households make the same decisions. Therefore, we can drop subscripts i and j . The aggregate production function, in the symmetric equilibrium, is then given by: $Y_t = (A_t L_t)^{1-\alpha} K_t^\alpha$, since $K_t = K_{i,t} = K_{jt}$ and $N_t = N_{i,t} = N_{jt}$. The market clearing

for the final good, in the symmetric equilibrium, requires that

$$Y_t = C_t + I_t + \chi(u_t)K_t^u + G_t + \frac{\psi_p}{2} \left[\frac{\Pi_t}{\tilde{\Pi}_{t-1}} - 1 \right]^2 Y_t \quad (217)$$

This completes the presentation of the DSGE model.

E.2 Stationary Allocation

We normalize the following variables :

$$y_t = Y_t/A_t \quad (218)$$

$$c_t = C_t/A_t \quad (219)$$

$$k_t = K_t/A_t \quad (220)$$

$$k_t^u = K_t^u/A_{t-1} \quad (221)$$

$$\mathbb{I}_t = I_t/A_t \quad (222)$$

$$w_t = W_t/(A_t P_t) \quad (223)$$

$$r_t^k = R_t^k/P_t \quad (224)$$

$$\lambda_t = \Lambda_t A_t \quad (225)$$

Definition 1 (Normalized Equilibrium) 18 endogenous variables $\{\lambda_t, i_t, c_t, y_t, \Pi_t, mc_t, \tilde{\Pi}_{t-1}, \Pi_t^w, \tilde{\Pi}_{t-1}^w, w_t, L_t, k_{t+1}^u, r_t^K, \mathbb{I}_t, q_t, u_t, k_t, G_{a,t}\}$, 8 endogenous shock processes $\{G_{\zeta,t}, \Xi_t, s_t, \mu_t, \lambda_t^p, \lambda_t^w, \lambda_t^{mp}, \lambda_t^g\}$, 8 exogenous shocks $\{\varepsilon_{\zeta,t}, \varepsilon_{\xi,t}, \varepsilon_{s,t}, \varepsilon_{\mu,t}, \varepsilon_{p,t}, \varepsilon_{w,t}, \varepsilon_{mp,t}, \varepsilon_{g,t}\}$ given initial values of k_{t-1}^u .

Consumption Euler Equation

$$\frac{\lambda_t}{G_{a,t}\Pi_t} = \beta(1 + i_t)\mathbb{E}_t^\theta \left[\frac{\lambda_{t+1}}{G_{a,t}G_{a,t+1}} \frac{1}{\Pi_t\Pi_{t+1}} \right] \quad (226)$$

$$\lambda_t = \frac{1}{c_t - \frac{hc_{t-1}}{G_{a,t}}} \quad (227)$$

Price-setting

$$(1 - \epsilon_{p,t}) + \epsilon_{p,t} mc_t - \psi_p \left(\frac{\Pi_t}{\tilde{\Pi}_{t-1}} - 1 \right) \frac{\Pi_t}{\tilde{\Pi}_{t-1}} + \psi_p \frac{\beta \Pi_t}{\lambda_t y_t} \mathbb{E}_t^\theta \left[\lambda_{t+1} \left(\frac{\Pi_{t+1}}{\tilde{\Pi}_t} - 1 \right) \frac{\Pi_{t+1}}{\tilde{\Pi}_t} \frac{y_{t+1}}{\Pi_t} \right] = 0 \quad (228)$$

$$\tilde{\Pi}_{t-1} = \bar{\Pi}^{1-\iota_p} \Pi_{t-1}^{\iota_p} \quad (229)$$

Wage-setting

$$\psi_w \left[\frac{\Pi_t^w}{\tilde{\Pi}_{t-1}^w} - 1 \right] \frac{\Pi_t^w}{\tilde{\Pi}_{t-1}^w} = \psi_w \beta \mathbb{E}_t^\theta \left[\frac{\Pi_{t+1}^w}{\tilde{\Pi}_t^w} - 1 \right] \frac{\Pi_{t+1}^w}{\tilde{\Pi}_t^w} + L_t \lambda_t \epsilon_{w,t} \left[\omega \frac{L_t^\nu}{\lambda_t} - \frac{\epsilon_{w,t} - 1}{\epsilon_{w,t}} w_t \right] \quad (230)$$

$$\tilde{\Pi}_{t-1}^w = G_a \bar{\Pi}^{1-\iota_w} (\exp(\varepsilon_{\zeta,t}) \exp(\varepsilon_{\xi,t}) \Pi_{t-1})^{\iota_w} \quad (231)$$

$$\Pi_t^w = \frac{w_t}{w_{t-1}} \Pi_t G_{a,t} \quad (232)$$

Capital Investment

$$k_{t+1}^u = \mu_t \left[1 - S \left(\frac{\mathbb{I}_t}{\mathbb{I}_{t-1}} \frac{G_{a,t}}{G_a} \right) \right] \mathbb{I}_t + (1 - \delta_k) \frac{k_t^u}{G_{a,t}} \quad (233)$$

$$q_t = \frac{\beta G_{a,t}}{\lambda_t} \mathbb{E}_t^\theta \left[\frac{\lambda_{t+1}}{G_{a,t} G_{a,t+1}} (r_{t+1}^K u_{t+1} - \chi(u_{t+1}) + q_{t+1}(1 - \delta_k)) \right] \quad (234)$$

$$\begin{aligned} & q_t \mu_t \left[1 - S \left(\frac{\mathbb{I}_t}{\mathbb{I}_{t-1}} \frac{G_{a,t}}{G_a} \right) - S' \left(\frac{\mathbb{I}_t}{\mathbb{I}_{t-1}} \frac{G_{a,t}}{G_a} \right) \frac{\mathbb{I}_t}{\mathbb{I}_{t-1}} \frac{G_{a,t}}{G_a} \right] \\ & + \frac{\beta G_{a,t}}{\lambda_t} \mathbb{E}_t^\theta \left[\mu_{t+1} \frac{\lambda_{t+1}}{G_{a,t}} q_{t+1} \frac{G_{a,t+1}}{G_a} \left(\frac{\mathbb{I}_{t+1}}{\mathbb{I}_t} \right)^2 S' \left(\frac{\mathbb{I}_{t+1}}{\mathbb{I}_t} \frac{G_{a,t+1}}{G_a} \right) \right] = 1 \end{aligned} \quad (235)$$

Capital Utilization Rate

$$k_t = u_t \frac{k_t^u}{G_{a,t}} \quad (236)$$

$$r_t^K = \chi'(u_t) \quad (237)$$

Production Technologies

$$y_t = k_t^\alpha L_t^{1-\alpha} \quad (238)$$

$$\frac{k_t}{L_t} = \frac{w_t}{r_t^k} \frac{\alpha}{1-\alpha} \quad (239)$$

$$mc_t = \frac{(r_t^k)^\alpha w_t^{1-\alpha}}{\alpha^\alpha (1-\alpha)^{1-\alpha}} \quad (240)$$

Government

$$\frac{1 + i_t}{1 + i_{ss}} = \left(\frac{1 + i_{t-1}}{1 + i_{ss}} \right)^{\rho_R} \left[\left(\frac{\Pi_t}{\bar{\Pi}} \right)^{\phi_\pi} Y_t^{\phi_y} \right]^{1-\rho_R} \exp(\lambda_t^{mp}) \quad (241)$$

Market Clearing

$$y_t = c_t + \mathbb{I}_t + \chi(u_t) \frac{k_t^u}{G_{a,t}} + \left(1 - \frac{1}{\lambda_t^g}\right) y_t \quad (242)$$

TFP Growth Rate

$$\log G_{a,t} = \log G_{\zeta,t} + (\log \Xi_t - \log \Xi_{t-1}) \quad (243)$$

E.3 Steady State

$$1 = \beta \frac{1}{G_a} \frac{1+i}{\Pi} \quad (244)$$

$$\lambda = \frac{G_a}{c(G_a - h)} \quad (245)$$

$$mc = \frac{\epsilon_p}{\epsilon_p - 1} \quad (246)$$

$$\frac{\omega L^\nu}{\lambda} = \frac{\epsilon_w - 1}{\epsilon_w} w \quad (247)$$

$$\Pi^w = \Pi G_a \quad (248)$$

$$\Pi = \bar{\Pi} \quad (249)$$

$$q = 1 \quad (250)$$

$$u = 1 \quad (251)$$

$$\left(1 - \frac{1 - \delta_k}{G_a}\right) k^u = \mathbb{I} \quad (252)$$

$$1 = \beta \left[\frac{1}{G_a} (r^K + (1 - \delta_k)) \right] \quad (253)$$

$$k = \frac{k^u}{G_a} \quad (254)$$

$$r^K = \chi'(1) \quad (255)$$

$$y = k^\alpha L^{1-\alpha} \quad (256)$$

$$r^k = \frac{\epsilon_p}{\epsilon_p - 1} \alpha \frac{y}{k} \quad (257)$$

$$w = \frac{\epsilon_p}{\epsilon_p - 1} (1 - \alpha) \frac{y}{L} \quad (258)$$

$$y = c + \mathbb{I} + \left(1 - \frac{1}{\lambda^g}\right) y \quad (259)$$

$$S(1) = S'(1) = 0; S'' > 0 \quad (260)$$

$$G_a = G_\zeta \quad (261)$$

E.4 Loglinearized Model

Consumption Euler Equation

$$\hat{\lambda}_t - \hat{G}_{a,t} - \hat{\pi}_t = \hat{i}_t + \mathbb{E}_t^\theta \left[\hat{\lambda}_{t+1} - \hat{G}_{a,t} - \hat{G}_{a,t+1} - \hat{\pi}_t - \hat{\pi}_{t+1} \right] \quad (262)$$

$$\hat{\lambda}_t + \frac{G_a}{G_a - h} \hat{c}_t - \frac{h}{G_a - h} \left(\hat{c}_{t-1} - \hat{G}_{a,t} \right) = 0 \quad (263)$$

Price-setting

$$\hat{\pi}_t = \beta \mathbb{E}_t^\theta [\hat{\pi}_{t+1} - \iota_p \hat{\pi}_t] + \iota_p \hat{\pi}_{t-1} + \frac{\epsilon_p - 1}{\psi_p} \hat{m} c_t + \hat{\lambda}_t^{p,*} \quad (264)$$

where $\hat{\lambda}_t^{p,*}$ is the normalized price-markup shock process. Let the un-normalized process be denoted with $\hat{\lambda}_t^p$. Then $\hat{\lambda}_t^{p,*} = \frac{\epsilon_p - 1}{\psi_p} \hat{\lambda}_t^p$. In steady state $\lambda^p = \frac{\epsilon_p}{\epsilon_p - 1}$

Wage-setting

$$\hat{\pi}_t^w = \beta \mathbb{E}_t^\theta \left[\hat{\pi}_{t+1}^w - \iota_w \hat{\pi}_t - \iota_w \hat{G}_{a,t+1} \right] + \iota_w \hat{\pi}_{t-1} + \iota_w \hat{G}_{a,t} + \frac{\epsilon_w \omega L^{1+\nu}}{\psi_w} \left[\nu \hat{L}_t - \hat{w}_t - \hat{\lambda}_t \right] + \hat{\lambda}_t^{w,*} \quad (265)$$

where $\hat{\lambda}_t^{w,*}$ is the normalized wage-markup shock process. Let the un-normalized wage markup process be denoted with $\hat{\lambda}_t^w$. Then $\hat{\lambda}_t^{w,*} = \frac{\epsilon_w \omega L^{1+\nu}}{\psi_w} \hat{\lambda}_t^w$. In steady state $\lambda^w = \frac{\epsilon_w}{\epsilon_w - 1}$

$$\hat{\pi}_t^w = \hat{w}_t - \hat{w}_{t-1} + \hat{\pi}_t + \hat{G}_{a,t} \quad (266)$$

Capital Investment

$$\hat{k}_{t+1}^u = \frac{\mathbb{I}}{k^u} \left(\hat{I}_t + \hat{\mu}_t \right) + \frac{1 - \delta_k}{G_a} \left(\hat{k}_t^u - \hat{G}_{a,t} \right) \quad (267)$$

$$\hat{q}_t - \hat{G}_{a,t} + \hat{\lambda}_t = \mathbb{E}_t^\theta \left[\hat{\lambda}_{t+1} - \hat{G}_{a,t} - \hat{G}_{a,t+1} + \frac{r^K}{r^K + 1 - \delta_k} \hat{r}_{t+1}^K + \frac{1 - \delta_k}{r^K + 1 - \delta_k} \hat{q}_{t+1} \right] \quad (268)$$

$$\hat{q}_t + \hat{\mu}_t - S''(1) \left(\hat{I}_t - \hat{I}_{t-1} + \hat{G}_{a,t} \right) + \beta S''(1) \mathbb{E}_t^\theta \left(\hat{I}_{t+1} - \hat{I}_t + \hat{G}_{a,t+1} \right) = 0 \quad (269)$$

Capital Utilization Rate

$$\hat{k}_t = \hat{u}_t + \hat{k}_t^u - \hat{G}_{a,t} \quad (270)$$

$$\hat{r}_t^K = \frac{\chi''(1)}{\chi'(1)} \hat{u}_t \quad (271)$$

Production Technologies

$$\hat{y}_t = \alpha \hat{k}_t + (1 - \alpha) \hat{L}_t \quad (272)$$

$$\hat{r}_t^K = \hat{w}_t + \hat{L}_t - \hat{k}_t \quad (273)$$

$$\hat{m}c_t = \alpha \hat{r}_t^K + (1 - \alpha) \hat{w}_t \quad (274)$$

Government

$$\hat{i}_t = \rho_R \hat{i}_{t-1} + (1 - \rho_R) (\phi_\pi \hat{\pi}_t + \phi_y \hat{y}_t) + \hat{\lambda}_t^{mp} \quad (275)$$

Market Clearing

$$\frac{1}{\lambda^g} \hat{y}_t = \frac{c}{y} \hat{c}_t + \frac{\mathbb{I}}{y} \hat{I}_t + \frac{\chi'(1)k}{y} \hat{u}_t + \frac{1}{\lambda^g} \hat{\lambda}_t^g \quad (276)$$

TFP Growth Rate

$$\hat{G}_{a,t} = \hat{G}_{\zeta,t} + \hat{\xi}_t - \hat{\xi}_{t-1} \quad (277)$$

$$\hat{a}_t = \hat{\zeta}_t + \hat{\xi}_t \quad (278)$$

where \hat{a}_t and $\hat{\zeta}_t$ are defined as log deviations of A_t and Z_t from their initial values.

Law of Motion of Shocks

$$\hat{G}_{\zeta,t} = \rho_\zeta \hat{G}_{\zeta,t-1} + \varepsilon_{\zeta,t} \quad (279)$$

$$\hat{\xi}_t = \rho_\xi \hat{\xi}_{t-1} + \varepsilon_{\xi,t} \quad (280)$$

$$\hat{\mu}_t = \rho_\mu \hat{\mu}_{t-1} + \varepsilon_{\mu,t} \quad (281)$$

$$\hat{\lambda}_t^{mp} = \rho_{mp} \hat{\lambda}_{t-1}^{mp} + \varepsilon_{mp,t} \quad (282)$$

$$\hat{\lambda}_t^g = \rho_g \hat{\lambda}_{t-1}^g + \varepsilon_{g,t} \quad (283)$$

$$\hat{\lambda}_t^{p,*} = \rho_p \hat{\lambda}_{t-1}^{p,*} + \varepsilon_{p,t} - \phi_p \varepsilon_{p,t-1} \quad (284)$$

$$\hat{\lambda}_t^{w,*} = \rho_w \hat{\lambda}_{t-1}^{w,*} + \varepsilon_{w,t} - \phi_w \varepsilon_{w,t-1} \quad (285)$$

Disturbances

$$\text{TFP growth shock} \quad \varepsilon_{\zeta,t} \sim N(0, \sigma_{\zeta}^2) \quad (286)$$

$$\text{Stationary TFP shock} \quad \varepsilon_{\xi,t} \sim N(0, \sigma_{\xi}^2) \quad (287)$$

$$\text{Noise shock} \quad \varepsilon_{s,t} \sim N(0, \sigma_s^2) \quad (288)$$

$$\text{MEI shock} \quad \varepsilon_{\mu,t} \sim N(0, \sigma_{\mu}^2) \quad (289)$$

$$\text{Monetary policy shock} \quad \varepsilon_{mp,t} \sim N(0, \sigma_{mp}^2) \quad (290)$$

$$\text{Government spending shock} \quad \varepsilon_{g,t} \sim N(0, \sigma_g^2) \quad (291)$$

$$\text{Price markup shock} \quad \varepsilon_{p,t} \sim N(0, \sigma_p^2) \quad (292)$$

$$\text{Wage markup shock} \quad \varepsilon_{w,t} \sim N(0, \sigma_w^2) \quad (293)$$

E.5 Diagnostic Kalman Filter

The solution of the medium-scale model featuring a diagnostic Kalman filter can be conveniently obtained by exploiting the existence of a perfect-information equivalent model (Blanchard, L’Huillier, and Lorenzoni 2013). First, write the diagnostic model in its RE representation. Then, use Lemma 2 of Blanchard et al. (2013) to get the perfect-information equivalent model. The latter can be solved using standard DSGE packages, such as Dynare.

E.6 Prior Distribution of the Parameters

The following parameters are fixed in the estimation procedure as shown in Table 6. The depreciation rate δ_k is fixed at 0.025, and the discount factor β is set to 0.99. The Dixit-Stiglitz aggregator for the goods (ϵ_p) and for labor services (ϵ_w) are fixed at 6. The parameter affecting the level of disutility from working (ω) is set to 1, and the steady-state share of government spending to final output is fixed at 1.2.

Table 6: Fixed Parameters

	Parameter	Value
β	Discount factor	0.99
δ_k	Capital depreciation rate	0.025
$1 - \frac{1}{\lambda_g}$	Government spending share	0.20
ω	Labor preference	1
ϵ_p	Elasticity of goods demand	6
ϵ_w	Elasticity of labor demand	6

Notes: The table reports parameters fixed in the estimation procedure for both DE and RE.

Prior distributions on price and wage rigidity parameters (ψ_p and ψ_w) are as in Gust, Herbst, López-Salido, and Smith (2017).

Table 7: Prior Distribution

Parameter	Description	Distribution	Mean	Std. dev
θ	diagnosticity	Normal	1	0.3

Notes: The table reports the prior distribution of structural parameters in the estimation procedure. The diagnosticity parameter θ is fixed at 0 under RE.

Figure 8: Posterior Distribution of Diagnosticity Parameter

Notes: Panels a) and b) depict the prior and posterior density of θ when the prior is centered at 1 and 0, respectively. The red, solid lines denote the prior distribution of θ , which follows a Normal distribution with standard deviation 0.3. The black, solid lines (the green, dashed vertical line) denote the posterior distribution (the posterior mean) of θ .

Table 8: Model-Implied Volatilities in the Medium-Scale DSGE Model

Variable	Diagnostic Expectations	Rational Expectations	Percentage Increase
Consumption	0.7939	0.6445	23%
Output	1.0055	0.8928	13%
Price Inflation	0.5308	0.4682	13%
Wage Inflation	0.9411	0.8498	11%
Real Rate	0.7532	0.5516	37%

Notes: The table reports the standard deviations of consumption growth, output growth, price inflation, wage inflation, and the real rate in the medium-scale DSGE model. The final column entitled “Percentage Increase” shows the percentage increase in standard deviation under the DE model relative to the RE benchmark (setting $\theta = 0$ along with parameter estimates in Table 1). There are eight structural shocks in the model, as in Blanchard et al. (2013): the TFP growth shock, TFP level shock, noise shock, marginal efficiency of investment (MEI) shock, price markup shock, wage markup shock, monetary policy shock, and government spending shock.

F Robustness

F.1 Prior on the Diagnosticity Parameter θ Centered at Zero

Table 9: Posterior Distribution: Prior Centered at Zero

Notes: Priors are given in Table 12.

F.4 Slope of Phillips Curve with Rotemberg Adjustment Costs

We compare the degree of price rigidity implied by our modeling of the Rotemberg quadratic adjustment costs model to the one implied by the Calvo counterpart. We find that using the Rotemberg costs does not change our inference about the slope of the Phillips curves (either price or wage) in the RE model.

The approach is similar to the one in Gust, Herbst, López-Salido, and Smith (2017). We calculate the slope of Phillips curves (price and wage) in our estimated models and compare those slope coefficients to the ones implied by the parameters reported in Smets and Wouters (2007) (henceforth SW) and Justiniano, Primiceri, and Tambalotti (2010) (henceforth JPT). We find that the slope coefficients are similar.

In a second exercise, we infer the Rotemberg adjustment cost parameter that is consistent with the slope implied by the reported posterior means in SW and JPT. We verify that the implied Rotemberg adjustment cost parameters are within our estimated credible intervals.

SW

Under Rotemberg adjustment costs, the slope coefficient (on marginal costs) in the price Phillips curve equation with rational expectations is given by

$$\kappa_p = \frac{\epsilon_p - 1}{(1 + \iota_p \beta \gamma^{1-\sigma_c}) \varphi_p}$$

where ϵ_p is elasticity of substitution across product varieties, ι_p is weight on previous period inflation rate Π_{t-1} , and hence governs indexation between previous period inflation rate Π_{t-1} and steady state inflation $\bar{\Pi}$, β is discount factor, and φ_p is the Rotemberg adjustment cost parameter.

Our estimated posterior mean values for these parameters are: $\beta = 0.9983$, $\iota_p = 0.2268$, $\gamma = 1.0042$, $\sigma_c = 1.3740$, and $\varphi_p = 383.13$. ϵ_p is fixed at 10. These parameters imply the slope coefficient of $\kappa_p^{Rotemberg} = 0.0192$.

Under Calvo pricing, the slope coefficient (on marginal costs) in the price Phillips curve equation with rational expectations is given by

$$\kappa_p^{Calvo} = \frac{(1 - \xi_p \beta \gamma^{1-\sigma_c})(1 - \xi_p)}{\xi_p (1 + \iota_p \beta \gamma^{1-\sigma_c}) ((\Phi - 1)\epsilon_p + 1)}$$

where $1 - \xi_p$ is the probability of resetting prices and Φ is one plus the share of fixed costs in production. The reported posterior mean values for these parameters (SW) are: $\xi_p = 0.66$, $\iota_p = 0.24$, $\beta = 0.9984$, $\gamma = 1.0043$, $\Phi = 1.60$, $\sigma_c = 1.38$. ϵ_p is fixed at

10. These parameters imply the slope coefficient of $\kappa_p^{Calvo} = 0.0203$. The conclusion is that both Calvo and Rotemberg lead to similar slopes of this Phillips curve.

Imposing that the slope coefficient to be identical across the two modeling choices, we can recover the implied Rotemberg adjustment cost parameter consistent with SW's parameters: Setting $\epsilon_p = 10$, $\beta = 0.9984$, $\iota_p = 0.24$, $\gamma = 1.0043$, $\sigma_c = 1.38$, as in SW implies a parameter of price adjustment cost of:

$$\varphi_p = \frac{\epsilon_p - 1}{(1 + \iota_p \beta \gamma^{1-\sigma_c}) \kappa_p^{Calvo}} \approx 357.76$$

As shown in Table 11, the posterior mean estimate of the Rotemberg pricing parameter ψ_p is 383.13 and the 90% credible interval covers values from 272.30 to 490.97 such that 357.76 is well within this credible band.

We now turn to the equivalent slope coefficient using Rotemberg wage adjustment cost, which with rational expectations is given by

$$\kappa_w = \frac{\epsilon_w L^{1+\nu}}{\varphi_w (1 + \beta \gamma^{1-\sigma_c})}$$

where ϵ_w is elasticity of substitution across labor varieties, ω is a scaling parameter in disutility of labor, L is the steady state labor, ν is the inverse of Frisch elasticity of labor supply, and φ_w is the Rotemberg wage adjustment cost parameter.

Our estimated posterior mean values for these parameters are: $\beta = 0.9983$, $L = 1.3998$, $\nu = 2.0293$, $\gamma = 1.0042$, $\sigma_c = 1.3740$, $\varphi_w = 2265.05$. ϵ_w is fixed at 10. These parameters imply the slope coefficient of $\kappa_w^{Rotemberg} = 0.0061$.

Under Calvo pricing, the slope of the wage Phillips curve equation is given by

$$\kappa_w^{Calvo} = \frac{(1 - \xi_w)(1 - \beta \gamma^{1-\sigma_c} \xi_w)}{\xi_w (1 + \beta \gamma^{1-\sigma_c}) (1 + (\lambda_w - 1) \epsilon_w)}$$

where $1 - \xi_w$ is the probability of resetting wages. The reported posterior mean values for these parameters (SW) are: $\xi_w = 0.7$, $\nu = 1.83$, and $\beta = 0.9984$, $\gamma = 1.0043$, and $\sigma_c = 1.38$. ϵ_w and λ_w are fixed at 10 and 1.5, respectively. These parameters imply the slope coefficient of $\kappa_w^{Calvo} = 0.0108$. The conclusion is that both Calvo and Rotemberg lead to similar slopes of this Phillips curve.

Imposing that the slope coefficient to be identical across the two modeling choices, we can recover the implied Rotemberg adjustment cost parameter consistent with SW's parameters: Setting $\beta = 0.9984$, $\gamma = 1.0043$, $\sigma_c = 1.38$, $\epsilon_w = 10$, $L = 1.4460$, $\nu = 1.83$,

and $\kappa_w = 0.0108$ implies a parameter of wage adjustment cost of:

$$\varphi_w = \frac{\epsilon_w L^{1+\nu}}{\kappa_w(1 + \beta\gamma^{1-\sigma_c})} \approx 1316.81$$

As shown in Table 11, the posterior mean estimate of the Rotemberg wage parameter ψ_w is 2265.05 and the 90% credible interval covers values from 1092.80 to 3374.99 such that 1316.72 is within this credible band.

JPT

Under Rotemberg adjustment costs, the slope coefficient (on marginal costs) in the price Phillips curve equation with rational expectations is given by

$$\kappa_p = \frac{\epsilon_p - 1}{(1 + \iota_p\beta)\varphi_p}$$

where ϵ_p is elasticity of substitution across product varieties, ι_p is weight on previous period inflation rate Π_{t-1} , and hence governs indexation between previous period inflation rate Π_{t-1} and steady state inflation $\bar{\Pi}$, β is discount factor, and φ_p is the Rotemberg adjustment cost parameter.

Our estimated posterior mean values for these parameters are: $\beta = 0.9986$, $\iota_p = 0.1964$, $\epsilon_p = 5.1339$, $\varphi_p = 116.43$. These parameters imply the slope coefficient of $\kappa_p^{Rotemberg} = 0.0297$.

Under Calvo pricing, the slope coefficient (on marginal costs) in the price Phillips curve equation with rational expectations is given by

$$\kappa_p^{Calvo} = \frac{(1 - \xi_p\beta)(1 - \xi_p)}{\xi_p(1 + \iota_p\beta)}$$

where $1 - \xi_p$ is the probability of resetting prices. The reported posterior mean values for these parameters (JPT) are: $\xi_p = 0.84$, $\iota_p = 0.24$, and $\beta = 0.9987$. These parameters imply the slope coefficient of $\kappa_p^{Calvo} = 0.0248$. The conclusion is that both Calvo and Rotemberg lead to similar slopes of this Phillips curve.

Imposing that the slope coefficient to be identical across the two modeling choices, we can recover the implied Rotemberg adjustment cost parameter consistent with JPT's parameters: Setting $\epsilon_p = 5.35$, $\beta = 0.9987$, $\iota_p = 0.24$ as in JPT implies a parameter of price adjustment cost of:

$$\varphi_p = \frac{\epsilon_p - 1}{(1 + \beta\iota_p)\kappa_p^{Calvo}} \approx 141.49$$

As shown in Table 13, the posterior mean estimate of the Rotemberg pricing parameter ψ_p is 116.43 and the 95% credible interval covers values from 84.65 to 147.57 such that 141.49 is within this credible band.

We now turn to the equivalent slope coefficient using Rotemberg wage adjustment cost, which with rational expectations is given by

$$\kappa_w = \frac{\epsilon_w \omega L^{1+\nu}}{\varphi_w (1 + \beta)}$$

where ϵ_w is elasticity of substitution across labor varieties, ω is a scaling parameter in disutility of labor, L is the steady state labor, ν is the inverse of Frisch elasticity of labor supply, and φ_w is the Rotemberg wage adjustment cost parameter.

Our estimated posterior mean values for these parameters are: $\beta = 0.9986$, $\epsilon_w = 8.3529$, $\omega = 0.4062$, $L = 1.2253$, $\nu = 4.2917$, $\varphi_w = 3204.29$. These parameters imply the slope coefficient of $\kappa_w^{Rotemberg} = 0.0016$.

Under Calvo pricing, the slope of the wage Phillips curve equation is given by

$$\kappa_w^{Calvo} = \frac{(1 - \xi_w \beta)(1 - \xi_w)}{\xi_w (1 + \beta) (1 + \nu(1 + \frac{1}{\lambda_w}))}$$

where $1 - \xi_w$ is the probability of resetting wages. The reported posterior mean values for these parameters (JPT) are: $\xi_w = 0.7$, $\nu = 3.79$, $\beta = 0.9987$, and $\lambda_w = 0.15$. These parameters imply the slope coefficient of $\kappa_w^{Calvo} = 0.0021$. The conclusion is that both Calvo and Rotemberg lead to similar slopes of this Phillips curve.

Imposing that the slope coefficient to be identical across the two modeling choices, we can recover the implied Rotemberg adjustment cost parameter consistent with JPT's parameters: Setting $\beta = 0.9987$, $\epsilon_w = 7.67$, $\omega = 0.1898$, $L = 1.46$, $\nu = 3.79$, and $\kappa_w = 0.0021$ implies a parameter of wage adjustment cost of:

$$\varphi_w = \frac{\epsilon_w \omega L^{1+\nu}}{\kappa_w (1 + \beta)} \approx 2125.08$$

As shown in Table 13, the posterior mean estimate of the Rotemberg wage parameter ψ_w is 3,204.29 and the 90% credible interval covers values from 720.56 to 5,835.47 such that 2,125.08 is well within this credible band.

G Data Appendix

Our data set spans the period 1954:III to 2004:IV. The series for Real GDP, Real Personal Consumption Expenditures, Real Personal Durable Consumption Expenditures, Real Gross Private Domestic Investment, Wages and the GDP Implicit Price Deflator are from the Bureau of Economic Analysis. Population and employment series are from the Bureau of Labor Statistics online database (series IDs LNS10000000Q and LNS12000000Q respectively). The Federal Funds Rate series is from the Federal Reserve Board online database (series ID H15/H15/RIFSPFF N.M).

The GDP series is constructed by dividing Real GDP by population. The consumption series is constructed by subtracting Real Personal Durable Consumption from Real Personal Consumption and dividing by population. The investment series is constructed by dividing the sum of Real Gross Investment and Real Personal Durable Consumption by population. The labor input series is constructed by dividing Employment by Population. Inflation is constructed by computing the quarterly log difference of the Price Deflator. The real wage is constructed by dividing Real Wages by the Price Deflator. The nominal interest rate is the effective Federal Funds Rate.

For SPF forecast data, we use the median forecast (across individual forecasters) as the consensus forecast. All forecasts we use are one quarter ahead forecasts. For the output (series ID RGDP), consumption (series ID RCONSUM), and investment (series ID RNRESIN) growth rate, we subtract these growth rate forecasts by actual population growth rate to obtain per capita forecasts. Inflation and the nominal interest rate are obtained from the GDP Price Deflator and the Treasury bill rate (series IDs PGDP and TBILL). Forecast data are available from 1968:IV to 2004:IV for the output growth rate and inflation, and from 1981:III to 2004:IV for the consumption and investment growth rate, and for the nominal interest rate.
